Introduction: Adenocarcinoma is the most common histologic type of lung cancer. To address advances in oncology, molecular biology, pathology, radiology, and surgery of lung adenocarcinoma, an international multidisciplinary classification was sponsored by the International Association for the Study of Lung Cancer, American Thoracic Society, and European Respiratory Society. This new adenocarcinoma classification is needed to provide uniform terminology and diagnostic criteria, especially for bronchioloalveolar carcinoma (BAC), the overall approach to small nonresection cancer specimens, and for multidisciplinary strategic management of tissue for molecular and immunohistochemical studies.

Methods: An international core panel of experts representing all three societies was formed with oncologists/pulmonologists, pathologists, radiologists, molecular biologists, and thoracic surgeons. A systematic review was performed under the guidance of the American Thoracic Society Documents Development and Implementation Committee. The search strategy identified 11,368 citations of which 312 articles met specified eligibility criteria and were retrieved for full text review. A series of meetings were held to discuss the development of the new classification, to develop the recommendations, and to write the current document. Recommendations for key questions were graded by strength and quality of the evidence according to the Grades of Recommendation, Assessment, Development, and Evaluation approach.

Results: The classification addresses both resection specimens, and small biopsies and cytology. The terms BAC and mixed subtype adenocarcinoma are no longer used. For resection specimens, new concepts are introduced such as adenocarcinoma in situ (AIS) and minimally invasive adenocarcinoma (MIA) for small solitary adenocarcinomas with either pure lepidic growth (AIS) or predominant lepidic growth with ≤5 mm invasion (MIA) to define patients who, if they undergo complete resection, will have 100% or near 100% disease-specific survival, respectively. AIS and MIA are usually nonmucinous but rarely may be mucinous. Invasive adenocarcinomas are classified by predominant pattern after using comprehensive histologic subtyping with lepidic (formerly most mixed subtype tumors with nonmucinous BAC), acinar, papillary, and solid patterns; micropapillary is added as a new histologic subtype. Variants include invasive mucinous adenocarcinoma (formerly mucinous BAC), colloid, fetal, and enteric adenocarcinoma. This classification provides guidance for small biopsies and cytology specimens, as approximately 70% of lung cancers are diagnosed in such samples. Non-small cell lung carcinomas (NSCLCs), in patients with advanced-stage disease, are to be classified into more specific types such as adenocarcinoma or squamous cell carcinoma.
Lung Adenocarcinoma Classification

NEED FOR A MULTIDISCIPLINARY APPROACH TO DIAGNOSIS OF LUNG ADENOCARCINOMA

One of the major outcomes of this project is the recognition that the diagnosis of lung adenocarcinoma requires a multidisciplinary approach. The classifications of lung cancer published by the World Health Organization (WHO) in 1967, 1981, and 1999 were written primarily by pathologists for pathologists.5–7 Only in the 2004 revision, relevant genetics and clinical information were introduced.4 Nevertheless, because of remarkable advances over the last 6 years in our understanding of lung adenocarcinoma, particularly in area of medical oncology, molecular biology, and radiology, there is a pressing need for a revised classification, based not on pathology alone, but rather on an integrated multidisciplinary platform. In particular, there are two major areas of interaction between specialties that are driving the need for our multidisciplinary approach to classification of lung adenocarcinoma: (1) in patients with advanced non–small cell lung cancer, recent progress in molecular biology and oncology has led to (a) discovery of epidermal growth factor receptor (EGFR) mutation and its prediction of response to EGFR tyrosine kinase inhibitors (TKIs) in adenocarcinoma patients8–11 and (b) the requirement to exclude a diagnosis of squamous cell carcinoma to determine eligibility for treatment with pemetrexed, (because of improved efficacy)12–15 or bevacizumab (because of toxicity)16,17 and (2) the emergence of radiologic-pathologic correlations between ground-glass versus solid or mixed opacities seen by computed tomography (CT) and BAC versus invasive growth by pathology have opened new opportunities for imaging studies to be used by radiologists, pulmonologists, and surgeons for predicting the histologic subtype of adenocarcinomas,18–21 patient prognosis,18–23 and improve preoperative assessment for choice of timing and type of surgical intervention.18–26

Although histologic criteria remain the foundation of this new classification, this document has been developed by pathologists in collaboration with clinical, radiology, molecular, and surgical colleagues. This effort has led to the development of terminology and criteria that not only define pathologic entities but also communicate critical information that is relevant to patient management (Tables 1 and 2). The classification also provides recommendations on strategic handling of specimens to optimize the amount of information to be gleaned. The goal is not only longer to solely provide the most accurate diagnosis but also to manage the tissue in a way that immunohistochemical and/or molecular studies can be performed to obtain predictive and prognostic data that will lead to improvement in patient outcomes.

For the first time, this classification addresses an approach to small biopsies and cytology in lung cancer diagnosis (Table 2). Recent data regarding EGFR mutation predicting responsiveness to EGFR-TKIs,8–11 toxicities,16 and therapeutic efficacy12–15 have established the importance of distinguishing squamous cell carcinoma from adenocarcinoma and non–small cell lung carcinoma (NSCLC) not otherwise specified (NOS) in patients with advanced lung cancer. Approximately 70% of lung cancers are diagnosed and

whenever possible for several reasons: (1) adenocarcinoma or NSCLC not otherwise specified should be tested for epidermal growth factor receptor (EGFR) mutations as the presence of these mutations is predictive of responsiveness to EGFR tyrosine kinase inhibitors, (2) adenocarcinoma histology is a strong predictor for improved outcome with pemetrexed therapy compared with squamous cell carcinoma, and (3) potential life-threatening hemorrhage may occur in patients with squamous cell carcinoma who receive bevacizumab. If the tumor cannot be classified based on light microscopy alone, special studies such as immunohistochemistry and/or mucin stains should be applied to classify the tumor further. Use of the term NSCLC not otherwise specified should be minimized.

Conclusions: This new classification strategy is based on a multidisciplinary approach to diagnosis of lung adenocarcinoma that incorporates clinical, molecular, radiologic, and surgical issues, but it is primarily based on histology. This classification is intended to support clinical practice, and research investigation and clinical trials. As EGFR mutation is a validated predictive marker for response and progression-free survival with EGFR tyrosine kinase inhibitors in advanced lung adenocarcinoma, we recommend that patients with advanced adenocarcinomas be tested for EGFR mutation. This has implications for strategic management of tissue, particularly for small biopsies and cytology samples, to maximize high-quality tissue available for molecular studies. Potential impact for tumor, node, and metastasis staging include adjustment of the size T factor according to only the invasive component (1) pathologically in invasive tumors with lepidic areas or (2) radiologically by measuring the solid component of part-solid nodules.

BAC, bronchioloalveolar carcinoma; IASLC, International Association for the Study of Lung Cancer; ATS, American Thoracic Society; ERS, European Respiratory Society.

The panel performed a systematic review with guidance by members of the ATS Documents Development and Implementation Committee. Key questions for this project were generated by each specialty group, and a search strategy was developed (Appendix 2, see Supplemental Digital Content 2 available at http://links.lww.com/JTO/A60). Searches were performed in June 2008 with an update in June 2009 resulting in 11,368 citations. These were reviewed to exclude articles that did not have any relevance to the topic of lung adenocarcinoma classification. The remaining articles were evaluated by two observers who rated them by a predetermined set of eligibility criteria using an electronic web-based survey program (www.surveymonkey.com) to collect responses.³¹ This process narrowed the total number of articles to 312 that were reviewed in detail for a total of 141 specific features, including 17 study characteristics, 35 clinical, 48 molecular, 16 radiologic, 16 molecular, and nine surgical (Appendix 2). These 141 features were summarized in an electronic database that was distributed to members of the core panel, including the writing committee. Articles chosen for specific data summaries were reviewed, and based on analysis of tables from this systematic review, recommendations were made according to the Grades of Recommendation, Assessment, Development, and Evaluation (GRADE).³²–³⁷ Throughout the rest of the document, the term GRADE (spelled in capital letters) must be distinguished from histologic grade, which is a measure of pathologic tumor differentiation. The GRADE system has two major components: (1) grading the strength of the recommendation and (2) evaluating the quality of the evidence.³² The strength of recommendations is based on weighing estimates of benefits versus downsides. Evidence was rated as high, moderate, or low or very low.³² The
quality of the evidence expresses the confidence in an estimate of effect or an association and whether it is adequate to support a recommendation. After review of all articles, a writing committee met to develop the recommendations with each specialty group proposing the recommendations, votes for or against the recommendation, and modifications were conducted after multidisciplinary discussion. If randomized trials were available, we started by assuming high quality but down-graded the quality when there were serious methodological limitations, indirectness in population, inconsistency in results, imprecision in estimates, or a strong suspicion of publication bias. If well-done observational studies were available, low-quality evidence was assumed, but the quality was upgraded when there was a large treatment effect or a large association, all plausible residual confounders would diminish the effects, or if there was a dose-response gradient. We developed considerations for good practice related to interventions that usually represent necessary and standard procedures of health care system—such as history taking and physical examination helping patients to make informed decisions, obtaining written consent, or the importance of good communication—when we considered them helpful. In that case, we did not perform a grading of the quality of evidence or strength of the recommendations.

Meetings
Between March 2008 and December 2009, a series of meetings were held, mostly at Memorial Sloan Kettering Cancer Center, in New York, NY, to discuss issues related to the classification of lung adenocarcinoma.

lung adenocarcinoma classification and to formulate this document. The core group established a uniform and consistent approach to the proposed types of lung adenocarcinoma.

Validation

Separate projects were initiated by individuals involved with this classification effort in an attempt to develop data to test the proposed system. These included projects on small biopsies,\(^5\) histologic grading,\(^6\) stage 1 adenocarcinomas,\(^7\) small adenocarcinomas from Japan, international multiple pathologist project on reproducibility of recognizing major histologic patterns of lung adenocarcinoma,\(^8\) molecular-histologic correlations, and radiologic-pathologic correlation focused on adenocarcinoma in situ (AIS), and minimally invasive adenocarcinoma (MIA).

The new proposals in this classification are based on the best available evidence at the time of writing this document. Nevertheless, because of the lack of universal diagnostic criteria in the literature, there is a need for future validation studies based on these standardized pathologic criteria with clinical, molecular, radiologic, and surgical correlations.

PATHOLOGIC CLASSIFICATION

Histopathology is the backbone of this classification, but lung cancer diagnosis is a multidisciplinary process requiring correlation with clinical, radiologic, molecular, and surgical information. Because of the multidisciplinary approach in developing this classification, we are recommending significant changes that should improve the diagnosis and classification of lung adenocarcinoma, resulting in therapeutic benefits.

Even after publication of the 1999 and 2004 WHO classifications,\(^9\) the former term BAC continues to be used for a broad spectrum of tumors including (1) solitary small noninvasive peripheral lung tumors with a 100% 5-year survival,\(^10\) (2) invasive adenocarcinomas with minimal invasion that have approximately 100% 5-year survival,\(^11\) (3) mixed subtype invasive adenocarcinomas,\(^12\) (4) mucinous and nonmucinous subtypes of tumors formerly known as BAC,\(^13\) and (5) widespread advanced disease with a very low survival rate.\(^14\) The consequences of confusion from the multiple uses of the former BAC term in the clinical and research arenas have been the subject of many reviews and editorials and are addressed throughout this document.\(^15\)

Pathology Recommendation 1

We recommend discontinuing the use of the term “BAC.” Strong recommendation, low-quality evidence.

Throughout this article, the term BAC (applicable to multiple places in the new classification, Table 3), will be referred to as “former BAC.” We understand this will be a major adjustment and suggest initially that when the new proposed terms are used, it will be accompanied in parentheses by “(formerly BAC).” This transition will impact not only clinical practice and research but also cancer registries future analyses of registry data.

CLASSIFICATION FOR RESECTION SPECIMENS

Multiple studies have shown that patients with small solitary peripheral adenocarcinomas with pure lepidic growth may have 100% 5-year disease-free survival.\(^16\) In addition, a growing number of articles suggest that patients with lepidic predominant adenocarcinomas (LPAs) with minimal invasion may also have excellent survival.\(^17\) Recent work has demonstrated that more than 90% of lung adenocarcinomas fall into the mixed subtype according to the 2004 WHO classification, so it has been proposed to use comprehensive histologic subtyping to make a semiquantitative assessment of the percentages of the various histologic components: acinar, papillary, micropapillary, lepidic, and solid and to classify tumors according to the predominant histologic subtype.\(^18\) This has demonstrated an improved ability to address the complex histologic heterogeneity of lung adenocarcinomas and to improve molecular and prognostic correlations.\(^19\)

The new proposed lung adenocarcinoma classification for resected tumors is summarized in Table 1.

Preinvasive Lesions

In the 1999 and 2004 WHO classifications, atypical adenomatous hyperplasia (AAH) was recognized as a preinvasive lesion for lung adenocarcinoma. This is based on multiple studies documenting these lesions as incidental findings in the adjacent lung parenchyma in 5 to 23% of resected lung adenocarcinomas and a variety of molecular findings that demonstrate a relationship to lung adenocarcinoma including cyclin D1,\(^20\) KRAS mutation,\(^21\) Kras polymorphism,\(^22\) EGFR mutation,\(^23\) p53 expression,\(^24\) loss of heterozygosity,\(^25\) methylation,\(^26\) telomerase overexpression,\(^27\) eukaryotic initiation factor 4E expression,\(^28\) epigenetic alterations in the Wnt pathway,\(^29\) and FHIT expression.\(^30\) Depending on the extensiveness of the search, AAH may be multiple in up to 7% of resected lung adenocarcinomas.\(^31\)

A major change in this classification is the official recognition of AIS, as a second preinvasive lesion for lung adenocarcinoma in addition to AAH. In the category of preinvasive lesions, AAH is the counterpart to squamous dysplasia and AIS the counterpart to squamous cell carcinoma in situ.

Atypical Adenomatous Hyperplasia

AAH is a localized, small (usually 0.5 cm or less) proliferation of mildly to moderately atypical type II pneumocytes and/or Clara cells lining alveolar walls and sometimes, respiratory bronchioles (Figures 1A, B).\(^32\) Gaps are

BAC, bronchioalveolar carcinoma.
slightly thickened, but preserved, alveolar walls. The tumor shows atypical pneumocytes proliferating along the preexisting alveolar walls. There is no invasive component. The slightly atypical pneumocytes are cuboidal and show gaps between the cells. Nuclei are hyperchromatic, and a few show nuclear enlargement and multinoucleation.

FIGURE 1. Atypical adenomatous hyperplasia. A, This 3-mm nodular lesion consists of atypical pneumocytes proliferating along preexisting alveolar walls. There is no invasive component. B, The slightly atypical pneumocytes are cuboidal and show gaps between the cells. Nuclei are hyperchromatic, and a few show nuclear enlargement and multinoucleation.

FIGURE 2. Nonmucinous adenocarcinoma in situ. A, This circumscribed nonmucinous tumor grows purely with a lepidic pattern. No foci of invasion or scarring are seen. B, The tumor shows atypical pneumocytes proliferating along the slightly thickened, but preserved, alveolar walls.

Usually seen between the cells, which consist of rounded, cuboidal, low columnar, or “peg” cells with round to oval nuclei (Figure 1B). Intranuclear inclusions are frequent. There is a continuum of morphologic changes between AAH and AIS. A spectrum of cellularity and atypia occurs in AAH. Although some have classified AAH into low- and high-grade types, grading is not recommended. Distinction between more cellular and atypical AAH and AIS can be difficult histologically and impossible cytologically.

AIS, Nonmucinous, and/or Mucinous
AIS (one of the lesions formerly known as BAC) is a localized small (≤3 cm) adenocarcinoma with growth restricted to neoplastic cells along preexisting alveolar structures (lepidic growth), lacking stromal, vascular, or pleural invasion. Papillary or micropapillary patterns and intraalveolar tumor cells are absent. AIS is subdivided into nonmucinous and mucinous variants. Virtually, all cases of AIS are nonmucinous, consisting of type II pneumocytes and/or Clara cells (Figures 2A, B). There is no recognized clinical significance to the distinction between type II or Clara cells, so this morphologic separation is not recommended. The rare cases of mucinous AIS consist of tall columnar cells with basal nuclei and abundant cytoplasmic mucin; sometimes they resemble goblet cells (Figures 3A, B). Nuclear atypia is absent or inconspicuous in both nonmucinous and mucinous AIS (Figures 2B and 3B). Septal widening with sclerosis is common in AIS, particularly the nonmucinous variant.

Tumors that meet criteria for AIS have formerly been classified as BAC according to the strict definition of the 1999 and 2004 WHO classifications and type A and type B adenocarcinoma according to the 1995 Noguchi classification. Multiple observational studies on solitary lung adenocarcinomas with pure lepidic growth, smaller than either 2 or 3 cm have documented 100% disease-free survival. Although most of these tumors are nonmucinous, 2 of the 28 tumors reported by Noguchi as types A and B in the 1995 study were mucinous. Small size (≤3 cm) and a discrete circumscribed border are important to exclude cases with miliary spread into adjacent lung parenchyma and/or lobar consolidation, particularly for mucinous AIS.

Pathology Recommendation 2
For small (≤3 cm), solitary adenocarcinomas with pure lepidic growth, we recommend the term “Adenocarcinoma in situ” that defines patients who should have 100% disease-specific survival, if the lesion is completely resected (strong recommendation, moderate quality evidence).

Remark: Most AIS are nonmucinous, rarely are they mucinous.

MIA, Nonmucinous, and/or Mucinous
MIA is a small, solitary adenocarcinoma (≤3 cm), with a predominantly lepidic pattern and ≤5 mm invasion in greatest dimension in any one focus. MIA is usually nonmucinous (Figures 4A–C) but rarely may be mucinous (Figures 5A, B). MIA is, by definition, solitary and discrete. The criteria for MIA can be applied in the setting of multiple tumors only if the other tumors are regarded as synchronous primaries rather than intrapulmonary metastases.

The invasive component to be measured in MIA is defined as follows: (1) histological subtypes other than a lepidic pattern (i.e., acinar, papillary, micropapillary, and/or solid) or (2) tumor cells infiltrating myofibroblastic stroma. MIA is excluded if the tumor (1) invades lymphatics, blood vessels, or pleura or (2) contains tumor necrosis. If multiple microinvasive areas are found in one tumor, the size of the largest invasive area should be measured in the largest dimension, and it should be ≤5 mm invasion.
Evidence for a category of MIA with 100% disease-free survival can be found in the 1995 article by Noguchi et al., where vascular or pleural invasion was found in 10% of the small solitary lung adenocarcinomas that otherwise met the former definition of pure BAC. Even these focally invasive tumors also showed 100% disease-free survival. Subsequent articles by Suzuki et al. and Sakurai et al. defined subsets of small lung adenocarcinomas with 100% disease-free survival using scar size less than 5 mm and stromal invasion in the area of bronchioloalveolar growth, respectively. More recently, articles by Yim et al., Borczuk et al., and Maeshima et al. have described patients with MIA defined similar to the above criteria, and these have demonstrated near 100% disease specific or very favorable overall survival. There is very limited data regarding mucinous MIA; however, this seems to exist. A mucinous MIA with a minor mixture of a nonmucinous component is being reported. The recent report by Sawada et al. of localized mucinous BAC may have included a few cases of mucinous AIS or MIA, but details of the pathology are not specific enough to be certain. A recent series of surgically resected solitary mucinous BAC did not document histologically whether focal invasion was present or not, so AIS versus MIA status cannot be determined, but all eight patients with tumors measuring ≤3 cm had 100% overall 5-year survival rates.

Presentation as a solitary mass, small size, and a discrete circumscribed border is important to exclude cases of military involvement of adjacent lung parenchyma and/or lobar consolidation, particularly for mucinous AIS.

Pathology Recommendation 3
For small (≤3 cm), solitary, adenocarcinomas with predominant lepidic growth and small foci of invasion measuring ≤0.5 cm, we recommend a new concept of “Minimally invasive adenocarcinoma” to define patients who have near 100%, disease-specific survival, if completely resected (strong recommendation, low-quality evidence).

Remark: Most MIA are nonmucinous, rarely are they mucinous.

Tumor Size and Specimen Processing Issues for AIS and MIA
The diagnosis of AIS or MIA cannot be firmly established without entire histologic sampling of the tumor. If tumor procurement is performed, it should be done strategically as discussed in the molecular section.

Because most of the literature on the topic of AIS and MIA deal with tumors 2.0 or 3.0 cm or less, there is insufficient evidence to support that 100% disease-free survival can occur in completely resected, solitary tumors suspected to be AIS or MIA that are larger than 3.0 cm. Until data validate 100% disease-free survival for completely resected, solitary, adenocarcinomas larger than 3.0 cm suspected to be AIS or MIA after complete sampling, the term “lepidic predominant adenocarcinoma, suspect AIS or MIA” is suggested. In such a tumor larger than 3.0 cm, particularly if it has not been completely sampled, the term “lepidic predominant adenocarcinoma” is best applied with a comment that the clinical behavior is uncertain and/or that an invasive component cannot be excluded.

Invasive Adenocarcinoma
As invasive adenocarcinomas represent more than 70 to 90% of surgically resected lung cases, one of the most important aspects of this classification is to present a practical way to address these tumors that are composed of a complex heterogeneous mixture of histologic subtypes. This complex mixture of histologic subtypes has presented one of the greatest challenges to classification of invasive lung adenocarcinomas. In recent years, multiple independent research groups have begun to classify lung adenocarcinomas according to the most predominant subtype. This approach provides better stratifi-
cation of the “mixed subtype” lung adenocarcinomas according to the 1999/2004 WHO Classifications and has allowed for novel correlations between histologic subtypes and both molecular and clinical features.\(^{43,44,69,95–102}\)

In the revised classification, the term “predominant” is appended to all categories of invasive adenocarcinoma, as most of these tumors consist of mixtures of the histologic subtypes (Figures 6A–C). This replaces the use of the term adenocarcinoma, mixed subtype. Semiquantitative recording of the patterns in 5% increments encourages the observer to identify all patterns that may be present, rather than focusing on a single pattern (i.e., lepidic growth). This method provides a basis for choosing the predominant pattern. Although most previous studies on this topic used 10% increments, using 5% allows for greater flexibility in choosing a predominant subtype when tumors have two patterns with relatively similar percentages; it also avoids the need to use 10% for small amounts of components that may be prognostically important such as micropapillary or solid patterns. Recording of these percentages also makes it clear to the reader of a report when a tumor has relatively even mixtures of several patterns versus a single dominant pattern. In addition, it provides a way to compare the histology of multiple adenocarcinomas (see later).\(^{102}\) This approach may also provide a basis for architectural grading of lung adenocarcinomas.\(^{43}\) A recent reproducibility study of classical and difficult selected images of the major lung adenocarcinoma subtypes circulated among a panel of 26 expert lung cancer pathologists documented kappa values of 0.77 ± 0.07 and 0.38 ± 0.14, respectively.\(^{45}\) This study did not test recognition of predominant subtype.

**Pathology Recommendation 4**

For invasive adenocarcinomas, we suggest comprehensive histologic subtyping be used to assess histologic patterns semiquantitatively in 5% increments, choosing a single predominant pattern. Individual tumors are then classified according to the predominant pattern and the percentages of the subtypes are also reported (weak recommendation, low-quality evidence).

**Histologic Comparison of Multiple Adenocarcinomas and Impact on Staging**

Comprehensive histologic subtyping can be useful in comparing multiple lung adenocarcinomas to distinguish multiple primary tumors from intrapulmonary metastases. This has a great impact on staging for patients with multiple lung adenocarcinomas. Recording the percentages of the various histologic types in 5% increments, not just the most predominant type, allows these data to be used to compare multiple adenocarcinomas, particularly if the slides of a previous tumor are not available at the time of review of the additional lung tumors.\(^{102}\) In addition to comprehensive histologic subtyping, other histologic features of the tumors such as cytologic (clear cell or signet ring features) or stromal (desmoplasia or inflammation) characteristics may be helpful to compare multiple tumors.\(^{102}\)

**Pathology Recommendation 5**

In patients with multiple lung adenocarcinomas, we suggest comprehensive histologic subtyping may facilitate in the comparison of the complex, heterogeneous mixtures of histologic patterns to determine whether the tumors are metastases or separate synchronous or metachronous primaries (weak recommendation, low-quality evidence).
LPA typically consists of bland pneumocytic cells (type II pneumocytes or Clara cells) growing along the surface of alveolar walls similar to the morphology defined in the above section on AIS and MIA (Figures 6A, B). Invasive adenocarcinoma is present in at least one focus measuring more than 5 mm in greatest dimension. Invasion is defined as (1) histological subtypes other than a lepidic pattern (i.e., acinar, papillary, micropapillary, and/or solid) or (2) myofibroblastic stroma associated with invasive tumor cells (Figure 6C). The diagnosis of LPA rather than MIA is made if the tumor (1) invades lymphatics, blood vessels, or pleura or (2) contains tumor necrosis. It is understood that lepidic growth can occur in metastatic tumors and invasive mucinous adenocarcinomas. Nevertheless, the specific term “Lepidic predominant adenocarcinoma (LPA)” in this classification defines a nonmucinous adenocarcinoma that has lepidic growth as its predominant component, and these tumors are now separated from invasive mucinous adenocarcinoma. The term LPA should not be used in the context of invasive mucinous adenocarcinoma with predominant lepidic growth.

In the categories of mixed subtype in the 1999/2004 WHO classifications and type C in the Noguchi classification,4,46 there was no assessment of the percentage of lepidic growth (former BAC pattern), so in series diagnosed according to these classification systems, most of the LPAs are buried among a heterogeneous group of tumors that include predominantly invasive adenocarcinomas. Nevertheless, several studies have shown lepidic growth to be associated with more favorable survival in small solitary resected lung adenocarcinomas with an invasive component.47,64,103–105 One recent study of stage I adenocarcinomas using this approach demonstrated 90% 5-year recurrence free survival.44

Pathology Recommendation 6

For nonmucinous adenocarcinomas previously classified as mixed subtype where the predominant subtype consists of the former nonmucinous BAC, we recommend use of the term LPA and discontinuing the term “mixed subtype” (strong recommendation, low-quality evidence).

Acinar predominant adenocarcinoma shows a majority component of glands, which are round to oval shaped with a central luminal space surrounded by tumor cells (Figure 6D).4 The neoplastic cells and glandular spaces may contain mucin. Acinar structures also may consist of rounded aggregates of tumor cells with peripheral nuclear polarization with central cytoplasm without a clear lumen. AIS with collapse may be difficult to distinguish from the acinar pattern. Nevertheless, when the alveolar architecture is lost and/or myofibroblastic stroma is present, invasive acinar adenocarcinoma is considered present. Cribriform arrangements are regarded as a pattern of acinar adenocarcinoma.106

Papillary predominant adenocarcinoma shows a major component of a growth of glandular cells along central fibrovascular cores (Figure 6E).4 This should be distinguished from tangential sectioning of alveolar walls in AIS. If a tumor has lepidic growth, but the alveolar spaces are filled with papillary structures, the tumor is classified as papillary adenocarcinoma. Myofibroblastic stroma is not needed to diagnose this pattern.

Micropapillary predominant adenocarcinoma has tumor cells growing in papillary tufts, which lack fibrovascular cores (Figure 6F).4 These may appear detached and/or connected to alveolar walls. The tumor cells are usually small and cuboidal with minimal nuclear atypia. Ring-like glandular structures may “float” within alveolar spaces. Vascular invasion and stromal invasion are frequent. Psammoma bodies may be seen.

The micropapillary pattern of lung adenocarcinoma was cited in the 2004 WHO classification in the discussion,4 but there were too few publications on this topic to introduce it as a formal histologic subtype.107–109 Although most of the studies have used a very low threshold for classification of adenocarcinomas as micropapillary, including as low as 1 to 5%,108,109 it has recently been demonstrated that tumors classified as micropapillary according to the predominant subtype also have a poor prognosis similar to adenocarcinomas with a predominant solid subtype.44 All articles on the topic of micropapillary lung adenocarcinoma in early-stage patients have reported data indicating that this is a poor prognostic subtype.95,108–119 Additional evidence for the aggressive behavior of this histologic pattern is the overrepresentation of the micropapillary pattern in metastases compared with the primary tumors, where it sometimes comprises only a small percentage of the overall tumor.43

Pathology Recommendation 7

In patients with early-stage adenocarcinoma, we recommend the addition of “micropapillary predominant adenocarcinoma,” when applicable, as a major histologic subtype due to its association with poor prognosis (strong recommendation, low-quality evidence).

Solid predominant adenocarcinoma with mucin production shows a major component of polygonal tumor cells forming sheets, which lack recognizable patterns of adenocarcinoma, i.e., acinar, papillary, micropapillary, or lepidic growth (Figure 6G).4 If the tumor is 100% solid, intracellular mucin should be present in at least five tumor cells in each of two high-power fields, confirmed with histochemical stains for mucin (Figure 6H).4 Solid adenocarcinoma must be distinguished from squamous cell carcinomas and large cell carcinomas both of which may show rare cells with intracellular mucin.

Variants

Rationale for Changes in Adenocarcinoma Histologic Variants

Rationale for separation of invasive mucinous adenocarcinoma (formerly mucinous BAC) from nonmucinous adenocarcinomas. Multiple studies indicate that tumors formerly classified as mucinous BAC have major clinical, radiologic, pathologic, and genetic differences from the tumors formerly classified as nonmucinous BAC (Table 4).55,77,120,121,125–127,136,145–148 In particular, these tumors show a very strong correlation with KRAS mutation, whereas nonmucinous adenocarcinomas are more likely to show EGFR mutation and only occasionally KRAS mutation (Table 4). Therefore, in
occurs in association with multiple histologic patterns.151,152 Features are now regarded as cytologic changes that may be associated with the solid subtype. They are not considered to be distinctive clinical or molecular features.

Rationale for including mucinous cystadenocarcinoma in colloid adenocarcinoma. Tumors formerly classified as “Mucinous cystadenocarcinoma” are very rare, and they probably represent a spectrum of colloid adenocarcinoma. Therefore, we suggest that these adenocarcinomas that consist of uni- or oligolocular cystic structures by imaging and/or gross examination be included in the category of colloid adenocarcinoma. For such tumors, a comment could be made that the tumor resembles that formerly classified as mucinous cystadenocarcinoma.

Rationale for removing clear cell and signet ring carcinoma as adenocarcinoma subtypes. Clear cell and signet ring cell features are now regarded as cytologic changes that may occur in association with multiple histologic patterns. Thus, their presence and extent should be recorded, but data are not available that show a clinical significance beyond a strong association with the solid subtype. They are not considered to be specific histologic subtypes, although associations with molecular features are possible such as the recent observation of a small basal oriented nuclei. Alveolar spaces often contain mucin. These tumors may show the same heterogeneous mixture of lepidic, acinar, papillary, and solid growth as in nonmucinous tumors. The clinical significance of reporting semiquantitative estimates of subtype percentages and the predominant histologic subtype similar to nonmucinous adenocarcinomas is not certain. When stromal invasion is seen, the malignant cells may show less cytoplasmic mucin and more atypia. These tumors differ from mucinous AIS and MIA by one or more of the following criteria: size (>3 cm), amount of invasion (>0.5 cm), mult-

Histologic Features

Invasive mucinous adenocarcinoma (formerly mucinous BAC) has a distinctive histologic appearance with tumor cells having a goblet or columnar cell morphology with abundant intracytoplasmic mucin (Figures 7A, B). Cytologic atypia is usually inconspicuous or absent. Alveolar spaces often contain mucin. These tumors may show the same heterogeneous mixture of lepidic, acinar, papillary, micro-papillary, and solid growth as in nonmucinous tumors. The clinical significance of reporting semiquantitative estimates of subtype percentages and the predominant histologic subtype similar to nonmucinous adenocarcinomas is not certain. When stromal invasion is seen, the malignant cells may show less cytoplasmic mucin and more atypia. These tumors differ from mucinous AIS and MIA by one or more of the following criteria: size (>3 cm), amount of invasion (>0.5 cm), mult-

![FIGURE 7. Invasive mucinous adenocarcinoma. A, This area of invasive mucinous adenocarcinoma demonstrates a pure lepidic growth. B, Nevertheless, elsewhere this tumor demonstrated invasion associated with desmoplastic stroma and an acinar pattern.](image-url)
tiple nodules, or lack of a circumscribed border with miliary spread into adjacent lung parenchyma.

There is a strong tendency for multicentric, multilobar, and bilateral lung involvement, which may reflect aerogenous spread. Mixtures of mucinous and nonmucinous tumors may rarely occur; then the percentage of invasive mucinous adenocarcinoma should be recorded in a comment. If there is at least 10% of each component, it should be classified as “Mixed mucinous and nonmucinous adenocarcinoma.” Invasive mucinous adenocarcinomas (formerly mucinous BAC) need to be distinguished from adenocarcinomas that produce mucin but lack the characteristic goblet cell or columnar cell morphology of the tumors that have historically been classified as mucinous BAC. When mucin is identified by light microscopy or mucin stains in adenocarcinomas that do not meet the above criteria, this feature should be reported in a comment after classifying the tumor according to the appropriate terminology and criteria proposed in this classification. This can be done by adding a descriptive phrase such as “with mucin production” or “with mucinous features” rather than the term “invasive mucinous adenocarcinoma.”

Pathology Recommendation 8

For adenocarcinomas formerly classified as mucinous BAC, we recommend they be separated from the adenocarcinomas formerly classified as nonmucinous BAC and depending on the extent of lepidic versus invasive growth that they be classified as mucinous AIS, mucinous MIA, or for overtly invasive tumors “invasive mucinous adenocarcinoma” (weak recommendation, low-quality evidence).

Colloid adenocarcinoma shows extracellular mucin in abundant pools, which distend alveolar spaces with destruction of their walls (Figure 8A). The mucin pools contain clusters of mucin-secreting tumor cells, which may comprise only a small percentage of the total tumor and, thus, be inconspicuous (Figure 8A).155,156 The tumor cells may consist of goblet cells or other mucin secreting cells. Colloid adenocarcinoma is found more often as a mixture with other adenocarcinoma histologic subtypes rather than as a pure pattern. A tumor is classified as a colloid adenocarcinoma when it is the predominant component; the percentages of other components should be recorded.150 Cystic gross and histologic features are included in the spectrum of colloid adenocarcinoma, but in most cases, this is a focal feature. Cases previously reported as mucinous cystadenocarcinoma are extremely rare, and now these should be classified as colloid adenocarcinoma with cystic changes. The cysts are filled with mucin and lined by goblet or other mucin secreting cells (Figure 8B). The lining epithelium may be discontinuous and replaced with inflammation including a granulomatous reaction or granulation tissue. Cytologic atypia of the neoplastic epithelium is usually minimal.157

Fetal adenocarcinoma consists of glandular elements with tubules composed of glycogen-rich, nonciliated cells that resemble fetal lung tubules (Figure 8C).4 Subnuclear vacuoles are common and characteristic. Squamoid morules may be seen within lumens. Most are low grade with a favorable outcome. High-grade tumors occur. When mixtures occur with other histologic subtypes, the tumor should be classified according to the predominant component.158 This tumor typically occurs in younger patients than other adenocarcinomas. Uniquely, these tumors appear driven by mutations in the beta-catenin gene, and the epithelial cells express aberrant nuclear and cytoplasmic staining with this antibody by immunohistochemistry.159,160 Nakatani et al. and Sekine et al.159,160 have suggested that up-regulation of components in the Wnt signaling pathway such as beta-catenin is important in low-grade fetal adenocarcinomas and in biphasic pulmonary blastomas in contrast to high-grade fetal adenocarcinomas.

Enteric differentiation can occur in lung adenocarcinoma, and when this component exceeds 50%, the tumor is classified as pulmonary adenocarcinoma with enteric differentiation. The enteric pattern shares morphologic and immunohistochemical features with colorectal adenocarcinoma.154 In contrast to metastatic colorectal adenocarcinoma, these tumors are histologically heterogeneous with some component that resembles primary lung adenocarcinoma such as lepidic growth. Recording of the percentages of these other components may be useful. The enteric pattern consists of glandular and/or papillary structures sometimes with a cribriform pattern, lined by tumor cells that are mostly tall-
columnar with nuclear pseudostratification, luminal necrosis, and prominent nuclear debris (Figure 8D).\textsuperscript{154} Poorly differentiated tumors may have a more solid pattern. These tumors show at least one immunohistologic marker of enteric differentiation (CDX-2, CK20, or MUC2). Consistent positivity for CK7 and expression of TTF-1 in approximately half the cases helps in the distinction from metastatic colorectal adenocarcinoma.\textsuperscript{154,161} CK7-negative cases may occur.\textsuperscript{162} Primary lung adenocarcinomas that histologically resemble colorectal adenocarcinoma but lack immunohistochemical markers of enteric differentiation are probably better regarded as lung adenocarcinomas with enteric morphology rather than pulmonary adenocarcinoma with enteric differentiation.\textsuperscript{163}

**CLASSIFICATION FOR SMALL BIOPSIES AND CYTOLOGY**

**Clinical Relevance of Histologic Diagnosis Drives Need to Classify NSCLC Further**

This section applies to pathologic diagnosis of the majority of patients with lung cancer due to presentation with locally advanced or metastatic disease. Because of the need for improved separation of squamous cell carcinoma from adenocarcinoma, as it determines eligibility for molecular testing and impacts on specific therapies, there is now greater clinical interest in application of additional pathology tools to refine further the diagnosis in small biopsies (bronchoscopic, needle, or core biopsies) and cytology specimens from patients with advanced lung cancer, when morphologic features are not clear.\textsuperscript{30,39,40,164,165} Patients with adenocarcinoma should be tested for EGFR mutations (see evidence in Clinical Recommendation section) because patients with EGFR mutation-positive tumors may be eligible for first-line TKI therapy.\textsuperscript{8–11} Adenocarcinoma patients are also eligible for pemetrexed\textsuperscript{12–15} or bevacizumab-based chemotherapy regimens (see Clinical Recommendation section).\textsuperscript{16,17}

**Pathology Recommendation 9**

For small biopsies and cytology, we recommend that NSCLC be further classified into a more specific histologic type, such as adenocarcinoma or squamous cell carcinoma, whenever possible (strong recommendation, moderate quality evidence).

**Data Driving Need to Classify NSCLC Further are Based Only on Light Microscopy**

All current data that justify the importance of the distinction between histologic types of NSCLC in patients with advanced lung cancer are based on light microscopy alone.\textsuperscript{8–16} Thus, the diagnosis for clinical work, research studies, and clinical trials should be recorded in a manner, so it is clear how the pathologist made their determination: based on light microscopy alone or light microscopy plus special studies.

**Pathology Consideration for Good Practice**

1. When a diagnosis is made in a small biopsy or cytology specimen in conjunction with special studies, it should be clarified whether the diagnosis was established based on light microscopy alone or whether special stains were required.

**Management of Tissue for Molecular Studies is Critical**

Strategic use of small biopsy and cytology samples is important, i.e., use the minimum specimen necessary for an accurate diagnosis, to preserve as much tissue as possible for potential molecular studies (Figure 9).\textsuperscript{166} Methods that use substantial amounts of tissue to make a diagnosis of adenocarcinoma versus squamous cell carcinoma, such as large panels of immunohistochemical stains or molecular studies, may not provide an advantage over routine light microscopy with a limited immunohistochemical workup.\textsuperscript{165}

**Pathology Consideration for Good Practice**

2. Tissue specimens should be managed not only for diagnosis but also to maximize the amount of tissue available for molecular studies.

3. To guide therapy for patients with advanced lung adenocarcinoma, each institution should develop a multidisciplinary team that coordinates the optimal approach to obtaining and processing biopsy/cytology specimens to provide expeditious diagnostic and molecular results.

**If Light Microscopic Diagnosis is Clearly Adenocarcinoma or Squamous Cell Carcinoma, Use These WHO Diagnostic Terms**

Squamous cell carcinoma and adenocarcinoma should be diagnosed on biopsy and cytological materials when the criteria for specific diagnosis of these tumor types in the 2004 WHO classification are met. Nevertheless, for tumors that do not meet these criteria, newly proposed terminology and criteria are outlined in Table 2 and Figure 9.\textsuperscript{4}

**Histologic Heterogeneity of Lung Cancer is an Underlying Complexity**

Because of histologic heterogeneity, small biopsy and/or cytology samples may not be representative of the total tumor, and there may be a discrepancy with the final histologic diagnosis in a resection specimen. Still, combined histologic types that meet criteria for adenosquamous carcinoma comprise less than 5% of all resected NSCLCs.\textsuperscript{4} A much more common difficulty in small biopsies or cytologies is classifying poorly differentiated tumors where clear differentiation is difficult or impossible to appreciate on light microscopy. The heterogeneity issue also makes it impossible to make the diagnosis of AIS, MIA, large cell carcinoma, or pleomorphic carcinoma in a small biopsy or cytology, because resection specimens are needed to make these interpretations. The term “large cell carcinoma” has been used in some clinical trials, but the pathologic criteria for that diagnosis are not defined, and it is not clear how these tumors were distinguished from NSCLC-NOS, as this diagnosis cannot be made in small biopsies or cytology, the type of
FIGURE 9. Algorithm for adenocarcinoma diagnosis in small biopsies and/or cytology. Step 1: When positive biopsies (fiber-optic bronchoscopy [FOB], transbronchial [TBBx], core, or surgical lung biopsy [SLBx]) or cytology (effusion, aspirate, washings, and brushings) show clear adenocarcinoma (ADC) or squamous cell carcinoma (SQCC) morphology, the diagnosis can be firmly established. If there is neuroendocrine morphology, the tumor may be classified as small cell carcinoma (SCLC) or non-small cell lung carcinoma (NSCLC), probably large cell neuroendocrine carcinoma (LCNEC) according to standard criteria (HIC positive, NE, negative, and MUC positive or negative). If there is no clear ADC or SQCC morphology, the tumor is regarded as NSCLC-not otherwise specified (NOS). Step 2: NSCLC-NOS can be further classified based on (a) immunohistochemical stains (b) mucin (DPAS or mucicarmine) stains, or (c) molecular data. If the stains all favor ADC: positive ADC markers (i.e., TTF-1 and/or mucin positive) with negative SQCC markers, then the tumor is classified as NSCLC, favor ADC. If SQCC markers (i.e., p63 and/or CK5/6) are positive with negative ADC markers, the tumor is classified as NSCLC, favor SQCC. If the ADC and SQCC markers are both strongly positive in different populations of tumor cells, the tumor is classified as NSCLC-NOS, with a comment it may represent adenosquamous carcinoma. If all markers are negative, the tumor is classified as NSCLC-NOS. See text for recommendations on NSCLCs with marked pleomorphic and overlapping ADC/SQCC morphology. †EGFR mutation testing should be performed in (1) classic ADC, (2) NSCLC, favor ADC, (3) NSCLC-NOS, and (4) NSCLC-NOS, possible adenosquamous carcinoma. In a NSCLC-NOS, if EGFR mutation is positive, the tumor is more likely to be ADC than SQCC. Step 3: If clinical management requires a more specific diagnosis than NSCLC-NOS, additional biopsies may be indicated (−ve = negative; +ve = positive; TTF-1, thyroid transcription factor-1; DPAS, diastase-periodic acid-Schiff with diastase; +ve: positive; e.g., IHC, immunohistochemistry; NE, neuroendocrine; CD, cluster designation; CK, cytokeratin; NB, of note). EGFR, epidermal growth factor receptor; DPAS, diastase-periodic acid Schiff.
Pathology Considerations for Good Practice

4. The terms AIS or MIA should not be diagnosed in small biopsies or cytology specimens. A noninvasive pattern is present in a small biopsy, it should be referred to as a lepidic growth pattern.

5. The term large cell carcinoma should not be used for diagnosis in small biopsy or cytology specimens and should be restricted to resection specimens where the tumor is thoroughly sampled to exclude a differentiated component.

Use Minimal Stains to Diagnose NSCLC, Favor Adenocarcinoma, or Favor Squamous Cell Carcinoma

In those cases where a specimen shows NSCLC lacking either definite squamous or adenocarcinoma morphology, immunohistochemistry may refine diagnosis (Figure 9, step 2). To preserve as much tissue as possible for molecular testing in small biopsies, the workup should be minimal. Realizing that new markers are likely to be developed, we suggest the initial evaluation use as only one adenocarcinoma marker and one squamous marker. At the present time, TTF-1 seems to be the single best marker for adenocarcinoma. TTF-1 provides the added value of serving as a pneumocyte marker that can help confirm a primary lung origin in 75 to 85% of lung adenocarcinomas. Cytokeratin 7 also tends to stain adenocarcinoma more often than squamous cell carcinoma. Other antibodies (34BE12 and S100A7) are less specific and sensitive for squamous differentiation. These data have been confirmed using resections where biopsies were interpreted as NSCLC and work on most needle aspirate specimens. It is possible that cocktails of nuclear and cytoplasmic markers (TTF-1/CK5/6 or p63/napsin-A) may allow for use of fewer immunohistochemical studies of multiple antibodies. Cases positive for an adenocarcinoma marker (i.e.,TTF-1) and/or mucin with a negative squamous marker (i.e., p63) should be classified as “NSCLC favor adenocarcinoma” (Figures 10A–C) and those that are positive for a squamous tumor, with at least moderate, diffuse staining, and a negative adenocarcinoma marker and/or mucin stains, should be classified as “NSCLC favor squamous cell carcinoma,” with a comment specifying whether the differentiation was detected by light microscopy and/or by special stains. These two small staining panels are generally mutually exclusive. If an adenocarcinoma marker such as TTF-1 is positive, the tumor should be classified as NSCLC, favor adenocarcinoma despite any expression of squamous markers. If the reactivity for adenocarcinoma versus squamous markers is positive in a different population of tumor cells, this may suggest adenosquamous carcinoma.

If tumor tissue is inadequate for molecular testing, there may be a need to rebiopsy the patient to perform testing that will guide therapy (step 3, Figure 9).

There may be cases where multidisciplinary correlation can help guide a pathologist in their evaluation of small biopsies and/or cytology specimens from lung adenocarcinomas. For example, if a biopsy showing NSCLC-NOS is obtained from an Asian, female, never smoker with ground-glass nodules (GGNs) on CT, the pathologist should know this information as the tumor is more likely to be adenocarcinoma and have an EGFR mutation.

Cytology is a Useful Diagnostic Method, Especially When Correlated with Histology

Cytology is a powerful tool in the diagnosis of lung cancer, in particular in the distinction of adenocarcinoma from squamous cell carcinoma. In a recent study, of 192 preoperative cytology diagnoses, definitive versus favored versus unclassified diagnoses were observed in 88% versus 8% versus 4% of cases, respectively. When compared with subsequent resection specimens, the accuracy of cytologic diagnosis was 93% and for definitive diagnoses, it was 96%. For the adenocarcinoma and squamous cell carcinoma cases, only 3% of cases were unclassified, and the overall accuracy was 96%. When immunohistochemistry was used in 9% of these cases, the accuracy was 100%.

Whenever possible, cytology should be used in conjunction with histology in small biopsies (Figure 10D).
In another study where small biopsies were evaluated in conjunction with cytology for the diagnosis of adenocarcinoma versus squamous cell carcinoma versus unclassified (NSCLC-NOS), the result for cytology was 70% versus 19% versus 11% and for biopsies, it was 72%, 22%, and 6%, respectively.\textsuperscript{180} Still when cytology was correlated with biopsy, the percentage of cases diagnosed as NSCLC-NOS was greatly reduced to only 4% of cases.\textsuperscript{180} In a small percentage of cases (<5%), cytology was more informative than histology in classifying tumors as adenocarcinoma or squamous cell carcinoma.\textsuperscript{180} The factors that contributed the greatest to difficulty in a specific diagnosis in both studies were poor differentiation, low specimen cellularity, and squamous histology.\textsuperscript{179,180}

**Pathology Consideration for Good Practice**

6. When paired cytology and biopsy specimens exist, they should be reviewed together to achieve the most specific and nondiscordant diagnoses.

**Preservation of Cell Blocks from Cytology Aspirates or Effusions for Molecular Studies**

The volume of tumor cells in biopsies may be small due to frequent prominent stromal reactions, so that there may be insufficient material for molecular analysis. Material derived from aspirates or effusions may have more tumor cells than a small biopsy obtained at the same time, so any positive cytology samples should be preserved as cell blocks, so that tumor is archived for immunohistochemical and molecular studies. Furthermore, these materials should be used judiciously in making the diagnosis to preserve as much material as possible for potential molecular studies.\textsuperscript{40,181–183} In a recent study, material from cell blocks prepared from 128 lung cancer cytology specimens was suitable for molecular analysis for \textit{EGFR} and \textit{KRAS} mutations in 126 (98%) of specimens.\textsuperscript{179}

**Pathology Consideration for Good Practice**

7. Cell blocks should be prepared from cytology samples including pleural fluids.

**NSCLC-NOS: If No Clear Differentiation by Morphology or Immunohistochemistry**

There will remain a minority of cases where the diagnosis remains NSCLC-NOS, as no differentiation can be established by routine morphology and/or immunohistochemistry (Figure 9, step 2). In the setting of a tumor with a negative adenocarcinoma marker (i.e., TTF-1), and only weak or focal staining for a squamous marker, it is best to classify the tumor as NSCLC-NOS rather than NSCLC, favor squamous cell carcinoma. These cases may benefit from discussion in a multidisciplinary setting (a) to determine the need for a further sample if subtyping will affect treatment; (b) whether molecular data should be sought, again if treatment will be defined by such data; (c) whether noninvasive features such as imaging characteristics (e.g., peripheral GGN supporting adenocarcinoma) favor a tumor subtype; and (d) whether clinical phenotype (e.g., female, never smoker, and Asian) may assist in determining future management (Figure 9, step 3).

**Pathology Recommendation 10**

We recommend that the term NSCLC-NOS be used as little as possible, and we recommend it be applied only when a more specific diagnosis is not possible by morphology and/or special stains (strong recommendation, moderate quality evidence).

**Pathology Consideration for Good Practice**

8. The term nonsquamous cell carcinoma should not be used by pathologists in diagnostic reports. It is a categorization used by clinicians to define groups of patients with several histologic types who can be treated in a similar manner; in small biopsies/cytology, pathologists should classify NSCLC as adenocarcinoma, squamous cell carcinoma, NSCLC-NOS, or other terms outlined in Table 2 or Figure 9.

**NSCLC-NOS: When Morphology and Immunohistochemistry are Conflicting**

Rarely, small samples may show either morphologic features of both squamous cell carcinoma and adenocarcinoma with routine histology or by immunohistochemical expression of both squamous and adenocarcinoma markers; these should be termed as “NSCLC-NOS” with a comment recording the features suggesting concurrent glandular and squamous cell differentiation, specifying whether this was detected by light microscopy or immunohistochemistry. As p63 expression can occur in up to one third of adenocarcinomas\textsuperscript{40,184,185} in a tumor that lacks squamous cell morphology, virtually all tumors that show coexpression of p63 and TTF-1 will be adenocarcinomas. It is possible that the tumor may be an adenosquamous carcinoma but that diagnosis cannot be established without a resection specimen showing at least 10% of each component. If TTF-1 and p63 positivity are seen in different populations of tumor cells, it is possible that this may be more suggestive of adenosquamous carcinoma than if these markers are coexpressed in the same tumor cells.

**Interpret Morphologic and Staining Patterns to Maximize Patient Eligibility for Therapies**

Presently, the recommendation for \textit{EGFR} mutation testing and candidacy for pemetrexed or bevacizumab therapy is for the diagnosis of (1) adenocarcinoma, (2) NSCLC-NOS, favor adenocarcinoma, or (3) NSCLC-NOS (see Clinical Recommendation section later). For this reason, in most NSCLC, the primary decision pathologists need to focus on, while interpreting small biopsies and cytology specimens, whether the tumor is a definite squamous cell carcinoma or NSCLC, favor squamous cell carcinoma versus one of the above diagnoses. Thus, when morphology or immunohistochemical findings are equivocal, pathologists need to keep in mind that a diagnosis of squamous cell carcinoma or NSCLC, favor squamous cell carcinoma will exclude them from histologically driven molecular testing or chemotherapy. In such
Pathology Consideration for Good Practice

9. The above strategy for classification of adenocarcinoma versus other histologies and the terminology in Table 2 and Figure 9 should be used in routine diagnosis and future research and clinical trials, so that there is uniform classification of disease cohorts in relationship to tumor subtypes and data can be stratified according to diagnoses made by light microscopy alone versus diagnoses requiring special stains.

Distinction of Adenocarcinoma from Sarcomatoid Carcinomas

Cases that show sarcomatoid features such as marked nuclear pleomorphism, malignant giant cells, or spindle cell morphology should be preferentially regarded as adenocarcinoma or squamous cell carcinoma if these features are clearly present, as this is apt to influence management. Nevertheless, pleomorphic carcinoma, carcinosarcoma, and blastoma are very difficult to diagnose in small specimens due to the limited ability to assess for mixed histologies. Nevertheless, if a small biopsy shows what is probably an adenocarcinoma with pleomorphism, a comment should be made, e.g., “NSCLC, favor adenocarcinoma, with giant and/or spindle cell features” (depending on which feature is identified).

Pathology Consideration for Good Practice

10. Tumors that show sarcomatoid features, such as marked nuclear pleomorphism, malignant giant cells, or spindle cell morphology, should be preferentially regarded as adenocarcinoma or squamous cell carcinoma if clear glandular or squamous features are present, as this is apt to influence management. If such features are not present, the term “poorly differentiated non-small cell carcinoma with giant and/or spindle cell features” (depending on what feature is present) should be used.

Distinction of Adenocarcinoma from Neuroendocrine Carcinomas

Some cases of NSCLC may suggest neuroendocrine (NE) morphology; these should be assessed with NE markers (CD56, chromogranin, and/or synaptophysin), so that a diagnosis of large cell NE carcinoma (LCNEC) can be suggested. The term NSCLC, possible LCNEC is usually the best term when this diagnosis is suspected as it is difficult to establish a diagnosis of LCNEC on small biopsies. In those lacking NE morphology, we recommend against using routine staining with NE markers, as immunohistochemical evidence of NE differentiation in otherwise definite adenocarcinoma and squamous cell carcinoma does not seem to affect prognosis or treatment.

Pathology Consideration for Good Practice

11. NE immunohistochemical markers should only be performed in cases where there is suspected NE morphology. If NE morphology is not suspected, NE markers should not be performed.

GRADING OF ADENOCARCINOMAS

No well-established histologic or cytologic grading system exists for lung adenocarcinoma. Most publications which grade adenocarcinomas do not cite specific morphologic criteria. The overall grade of a tumor is typically determined by the component with the worst grade. Only a few studies have evaluated detailed morphologic grading systems.41,188–191 The primary approaches are based on architectural and/or nuclear attributes. Nevertheless, the following histologic features are promising candidates for components of a grading system. By architecture, the following prognostic associations have been reported: poor (solid41,43,44,53,69 and micropapillary),43,44,108,109 favorable (nonmucinous lepidic43,44,46,192 [formerly BAC]), and intermediate (papillary and acinar).43,44 Thus, comprehensive histologic subtyping method and subclassification of invasive tumors by the predominant subtype may be a simple way to develop the architectural grade of lung adenocarcinomas,43,44 similar to the Gleason grading system for prostate cancer.193 By nuclear criteria, preliminary data suggest poor prognosis may be associated with large nuclei and variability in nuclear size and shape.190,191,194 As stated earlier in the text, histologic grading should not be confused with the GRADE method of formulating recommendations and weighing evidence.190,191

STRATEGIC USE OF PATHOLOGIC SPECIMENS FOR MOLECULAR STUDIES

With the emerging importance of molecular diagnostics to guide therapy, a multidisciplinary approach is needed to set a consistent strategy for obtaining and preserving tissue samples optimized to perform studies such as DNA sequence analysis, fluorescence in situ hybridization (FISH), and, in some settings, RNA-based studies. It is not yet possible to provide specific guidelines on how to do this in the current document because of the wide variation in infrastructure and expertise from one institution to another. Still, this process begins with the method of obtaining tissue (fine needle aspiration [FNA], core or transbronchial biopsy, and surgical resection) and continues with the processing of the specimen in the pathology department, to delivery of material for molecular analysis, and communication of the molecular results in pathology reports.

If a portion of a sampled tumor is snap frozen for molecular studies, a few considerations exist as regards resection specimens. As most critical molecular studies can be performed from formalin-fixed paraffin-embedded tissue, there is a need for frozen samples only for certain techniques such as comparative genomic hybridization (CGH) and gene expression profiling. If frozen tissue is being obtained from tumors with lepidic predominant tumors where AIS or MIA is in the differential diagnosis, efforts should be made to
ascertain whether this frozen piece has an invasive component. The CT and gross appearance of the lesion should be considered to ensure a solid component is sampled in a tumor that appeared part solid on CT. Another approach is to perform a frozen section from the tissue saved for storage in a freezer.

Small biopsies and/or cytologic samples including pleural fluids can be used for many molecular analyses. \(^{179–181,195–205}\) EGFR mutation testing and KRAS mutation testing are readily performed on these specimens. \(^{179–181,195–199,203–205}\) Formalin-fixed paraffin-embedded samples can be used effectively for polymerase chain reaction-based mutation testing and for FISH or chromogenic in situ hybridization (CISH) testing for gene amplification and for immunohistochemistry. Cytology smears can be analyzed for immunohistochemical and certain molecular studies, but it is far preferable if cell blocks are available. Manual or laser-guided microdissection may enrich tumor cells for molecular studies. Assessment of EGFR mutations helps in selecting patients to be treated with EGFR-TKIs. Molecular testing in the setting of clinical trials can stratify patients by results of gene expression or markers of sensitivity to specific cytotoxic agents such as excision repair cross-complementation group 1 or breast cancer 1 for platinum, ribonucleotide reductase M1 for gemcitabine or thymidylate synthase for antifolates. \(^{206–211}\)

**Summary of Pathology Recommendations**

1. We recommend discontinuing the use of the term “BAC” (strong recommendation, low-quality evidence).

2. For small (\(\leq 3\) cm), solitary adenocarcinomas with pure lepidic growth, we recommend the term “Adenocarcinoma in situ” that defines patients who should have 100% disease-specific survival, if the lesion is completely resected (strong recommendation, moderate quality evidence). Remark: Most AIS are nonmucinous, rarely are they mucinous.

3. For small (\(\leq 3\) cm), solitary, adenocarcinomas with predominant lepidic growth and small foci of invasion measuring \(\leq 0.5\) cm, we recommend a new concept of “Minimally invasive adenocarcinoma” to define patients who should have near 100%, disease-specific survival, if completely resected (strong recommendation, low-quality evidence). Remark: Most MIA are nonmucinous, rarely are they mucinous.

4. For invasive adenocarcinomas, we suggest comprehensive histologic subtyping be used to assess histologic patterns semiquantitatively in 5% increments, choosing a single predominant pattern. We also suggest that individual tumors be classified according to the predominant pattern and that the percentages of the subtypes be reported (weak recommendations and low-quality evidence).

5. In patients with multiple lung adenocarcinomas, we suggest comprehensive histologic subtyping in the comparison of the complex, heterogeneous mixtures of histologic patterns to determine whether the tumors are metastases or separate synchronous or metachronous primaries (weak recommendation, low-quality evidence).

6. For nonmucinous adenocarcinomas previously classified as mixed subtype where the predominant subtype consists of the former nonmucinous BAC, we recommend use of the term LPA and discontinuing the term “mixed subtype” (strong recommendation, low-quality evidence).

7. In patients with early-stage adenocarcinoma, we recommend the addition of “micropapillary predominant adenocarcinoma,” when applicable, as a major histologic subtype due to its association with poor prognosis (strong recommendation, low-quality evidence).

8. For adenocarcinomas formerly classified as mucinous BAC, we recommend that they be separated from the adenocarcinomas formerly classified as nonmucinous BAC and depending on the extent of lepidic versus invasive growth that they be classified as mucinous AIS, mucinous MIA, or for overly invasive tumors “invasive mucinous adenocarcinoma” (weak recommendation, low-quality evidence).

9. For small biopsies and cytology, we recommend that NSCLC be further classified into a more specific type, such as adenocarcinoma or squamous cell carcinoma, whenever possible (strong recommendation, moderate quality evidence).

10. We recommend that the term NSCLC-NOS be used as little as possible, and we recommend it be applied only when a more specific diagnosis is not possible by morphology and/or special stains (strong recommendation, moderate quality evidence).

**Summary of Pathology Considerations for Good Practice**

1. When a diagnosis is made in a small biopsy or cytology specimen in conjunction with special studies, it should be clarified whether the diagnosis was established based on light microscopy alone or whether special stains were required.

2. Tissue specimens should be managed not only for diagnosis but also to maximize the amount of tissue available for molecular studies.

3. To guide therapy for patients with advanced lung adenocarcinoma, each institution should develop a multidisciplinary team that coordinates the optimal approach to obtaining and processing biopsy/cytology specimens to provide expeditious diagnostic and molecular results.

4. The terms AIS or MIA should not be used in small biopsies or cytology specimens. If a noninvasive pattern is present in a small biopsy, it should be referred to as lepidic growth.

5. The term large cell carcinoma should not be used for diagnosis in small biopsy or cytology specimens and should be restricted to resection specimens where the tumor is thoroughly sampled to exclude a differentiated component.
6. When paired cytology and biopsy specimens exist, they should be reviewed together to achieve the most specific and nondiscordant diagnoses.

7. Cell blocks should be prepared from cytology samples including pleural fluids.

8. The term nonsquamous cell carcinoma should not be used by pathologists in diagnostic reports. It is a categorization used by clinicians to define groups of patients with several histologic types who can be treated in a similar manner; in small biopsies/cytology, pathologists should classify NSCLC as adenocarcinoma, squamous cell carcinoma, NSCLC-NOS, or other terms outlined in Table 2 or Figure 9.

9. The above strategy for classification of adenocarcinoma versus other histologies and the terminology in Table 2 and Figure 9 should be used in routine diagnosis and future research and clinical trials, so that there is uniform classification of disease cohorts in relationship to tumor subtypes and data can be stratified according to diagnoses made by light microscopy alone versus diagnoses requiring special stains.

10. Tumors that show sarcomatoid features, such as marked nuclear pleomorphism, malignant giant cells, or spindle cell morphology, should be preferentially regarded as adenocarcinoma or squamous cell carcinoma if clear glandular or squamous features are present, as this is apt to influence management. If such features are not present, the term “poorly differentiated non-small cell carcinoma with giant and/or spindle cell features” (depending on what feature is present) should be used.

11. NE immunohistochemical markers should only be performed in cases where there is suspected NE morphology. If NE morphology is not suspected, NE markers should not be performed.

Pathology Research Recommendations

1. Criteria for MIA are based on limited published data and require further validation. Persistent questions include what is the optimal method for measuring the size of the invasive component? Is 0.5 cm the best size cut off? If multiple areas of invasion are present, should the greatest dimension of the largest invasive focus be used or the total size multiplied times the percentage of the invasive components? What should be the impact of scar size or prominent stromal desmoplasia and stromal inflammation on determining size of the invasive component? Should criteria for MIA be different for mucinous versus nonmucinous tumors?

2. Lepidic growth may also be composed of neoplastic cells with nuclear atypia resembling that of the adjacent invasive patterns. Whether there is any clinical implication is unknown. That is, it is not established if this is in situ or invasive carcinoma.

3. The level of reproducibility for identifying predominant histologic patterns is untested. In particular, how should the lepidic pattern be distinguished from other invasive patterns such as acinar and papillary?

4. Do tumors that meet criteria for MIA have 100% disease-free survival if the invasive component is predominantly solid, micropapillary or if they show giant cell and spindle cell components that fail to qualify for a diagnosis pleomorphic carcinoma?

5. What is the long-term follow-up for completely resected solitary mucinous MIA? Can this be the initial presentation for multifocal invasive mucinous adenocarcinoma?

6. Does the micropapillary pattern have a similar poor prognostic significance in advanced stage and early stage?

7. Is there any prognostic significance to the aggressive micropapillary or solid components when present in relatively small amounts if they do not represent the predominant pattern? If so, what percentage is needed for such significance?

8. Is immunohistochemical testing using EGFR mutation-specific antibodies a reliable method for predicting the presence of an EGFR mutation?

9. It is unknown whether there is any added value provided by refining NSCLC-NOS via immunohistochemistry on small biopsies or cytology samples. This requires assessment in future trials using systemic therapy.

10. Additional markers for squamous or adenocarcinoma differentiation, such as desmocoglin-3 or desmocollin for squamous cell carcinoma or napsin-A for adenocarcinoma, need further evaluation.

11. The ability of pathologists to distinguish AIS from invasive disease at frozen section is not proven.

12. Currently, we cannot recommend any specific grading system. Further investigation is needed to determine whether the optimal grading system should include architectural versus nuclear assessment or both.

13. In specimens from metastatic sites, is there any clinical significance to recognizing histologic patterns, including the predominant pattern?

CLINICAL FEATURES

Several important clinical facts have had a significant impact on this classification: (1) adenocarcinoma histology is a strong predictor for outcome to pemetrexed therapy in advanced-stage patients.13–15 (2) Distinction between adenocarcinoma or other non-small cell histologies and squamous cell carcinoma is important because of potential life-threatening hemorrhage in patients with squamous cell carcinoma who receive bevacizumab therapy.16 (3) EGFR mutation is a validated predictive marker for response and progression-free survival (PFS) with EGFR-TKIs in the first-line therapy in advanced lung adenocarcinoma.8,215–218 (4) Molecular markers are an important evolving area in evaluation and management of patients with lung adenocarcinoma.219 More data are needed regarding other molecular markers beyond EGFR mutation, such as KRAS mutation, EGFR gene copy number,
Biopsy and Pathology Issues for the Clinician

After initial evaluation, a plan for an invasive procedure to obtain a diagnosis and complete staging should be made in a multidisciplinary setting. The site for the biopsy should be chosen to yield the maximal information with the least risk. A key element in determining the type of procedure is the need to obtain adequate tissue for all pathologic and molecular evaluations (e.g., mutation analysis and immunohistochemistry).

For sampling a peripheral nodular lesion that contains a solid component, the suitable invasive procedures are transbronchial biopsy such as CT-guided biopsies, bronchoscopy/navigation-assisted bronchoscopy, sublobar resection, or lobectomy (e.g., by video-assisted thoracic surgery, VATS, or thoracoscopy). Either a core biopsy or a FNA with a cell block will reliably obtain adequate tissue. For mediastinal involvement, sampling can be achieved by blind TBNA, endobronchial endoscopy (endobronchial ultrasound) -guided TBNA, EUS-guided FNA, mediastinoscopy, VATS, or Chamberlain procedure. For patients with recurrent disease, repeat biopsy can be useful not only to confirm the diagnosis but also the molecular profile.

Prognostic and Predictive Factors

Multiple clinical, pathologic, and molecular factors have been explored for their association with patient outcome. To facilitate the discussion, we divided them into two categories although both categories are prognostic factors in the strict sense: prognostic factors, which dictate the virulence of the disease (e.g., progression and recurrence), and predictive factors, which are correlated with the outcome for specific therapies. Predictive and prognostic factors may overlap; however, they are often different.

The main independent clinical prognostic factors for patients with lung adenocarcinoma are stage, performance status, age, and sex. The independent prognostic value of stage exists whether using clinical or pathological staging. Data also suggest that smoking history may be an independent prognostic factor.

Although clinical factors provide important prognostic information, recently there has been greater focus on predictive factors for specific therapies, initially focusing on histology. In early clinical trials of erlotinib and gefitinib, some patients with good responses to these drugs were those with adenocarcinoma with lepidic growth patterns (formerly known as BAC). This led to trials of gefitinib and erlotinib in patients formerly diagnosed with BAC. West et al. reported the results of a Southwest Oncology Group trial in which 17% of patients had a response to gefitinib. Similarly, Miller et al. reported a 22% response rate to erlotinib in patients formerly diagnosed with BAC or adenocarcinoma with BAC features. In the new classification, many of these tumors would be regarded to be invasive adenocarcinomas with varying degrees of lepidic growth.

Although histology will continue to play an important predictive role, recently the use of molecular markers for predicting response to therapy has become more prominent, particularly after the discovery of EGFR mutations and their association with sensitivity to erlotinib and gefitinib. Although KRAS mutations were identified in patients with NSCLC more than 20 years ago, their clinical role as predictive and prognostic biomarkers remains controversial. Several phase 2 clinical trials verified use of EGFR mutations as predictors of response to erlotinib and gefitinib. EGFR mutations occur most frequently in East Asian patients and in those patients with little or no smoking history. The EGFR mutations that are most common and recognized to be of greatest clinical significance are somatic point mutations in exon 19 (L858R). The Iressa Pan Asian Survival Study trial, molecular subset analysis showed that PFS benefit was limited to the patients with EGFR mutation (hazard ratio [HR]: 0.48, 95% confidence interval [CI]: 0.36 – 0.64) and that gefitinib therapy was detrimental for those without mutations (HR: 2.85, 95% CI: 2.05–3.98).

Other molecular predictors of outcome have also been explored for erlotinib and gefitinib treatment. Retrospective analysis of data from the Iressa Survival Evaluation in Lung Cancer study showed that EGFR copy number and protein expression were predictive of significantly better overall survival after treatment with gefitinib. A multivariate analysis of data from the Canadian BR.21, phase 3 randomized, placebo-controlled trial of erlotinib in advanced NSCLC showed that EGFR copy number (but not EGFR mutation...
status) was associated with worse survival (HR: 1.9, 95% CI: 1.1–3.4) and a better response to erlotinib (p = 0.005), after controlling for race, performance status, weight loss, smoking history, prior treatment, and response to prior treatment.236 In a second-line, chemotherapy controlled phase III study (INTEREST) comparing gefitinib with docetaxel, overall survival was similar in the two arms, and there were no statistically significant interactions between treatment and EGFR copy number, protein expression, or mutation status.234 The results of all three of these studies may be influenced by inclusion of large numbers of patients with histologies other than adenocarcinoma and should be regarded as exploratory.234–236

For treatment of advanced NSCLC, response and outcome to EGFR-TKIs have been demonstrated in most studies to be better predicted by EGFR mutation testing rather than copy number or immunohistochemistry. In a phase II study of erlotinib-treated patients, multivariate analysis of molecular predictors showed that EGFR mutations, but not copy number, was predictive of response to erlotinib with a response of 83% in patients with EGFR mutations versus 7% in those without (p < 0.01).198 In this study, immunohistochemistry was not predictive of response.198 Another study by Sholl et al.237 found EGFR mutation status, but not FISH, CISH, or immunohistochemistry, was useful for predicting response and PFS for TKI therapy. The recent development of new mutation-specific antibodies for EGFR exon 19 deletion and L858R mutation seems to be much more reliable in predicting EGFR mutation status, and these need to be evaluated in future clinical trials.238–240 In the Iressa Pan Asian Survival Study, in FISH+ patients, gefitinib was worse than chemotherapy if those patients lacked EGFR mutations.241 All these studies used RECIST to measure response to therapy.8–11,198,234–236,241

More recently, investigators have noted that all NSCLC histologies other than squamous cell carcinoma seem to garner more benefit from two drugs, pemetrexed for efficacy and bevacizumab for avoidance of toxicity. Nevertheless, most of the analyses are subgroup analyses with the known shortcomings. Pemetrexed, a multitargeted antifolate agent, seems to have greater activity in NSCLCs with nonsquamous histology (adenocarcinoma and NSCLC-NOS), with the greatest proportion of benefit observed in patients with adenocarcinomas as demonstrated in two phase 3 trials.12–15 In a phase 3 trial, comparing cisplatin/pemetrexed with cisplatin/gemcitabine, preplanned subgroup analysis, revealed median overall survival was significantly better for patients with adenocarcinoma (12.6 versus 10.9 months, HR = 0.81, 95% CI: 0.71–0.99, p = 0.03) and large cell carcinoma (would be called NSCLC-NOS by the current proposal), overall survival of 10.4 versus 6.7 months (HR = 0.67; CI: 0.48–0.96), whereas no benefit was seen with squamous cell carcinoma or with all histologies combined.13 Follow-up analysis of the same patients from this phase 3 study but focusing on those without grade 3 or 4 drug toxicity, a similar benefit for overall survival was found in patients with nonsquamous histology comparing cisplatin pemetrexed with cisplatin/gemcitabine (median survival of 5.6 months versus 2.8 months, respectively, HR = 0.64, 95% CI: 0.56–0.72, p < 0.001).12

Ciuleanu et al. showed in a phase 3 trial comparing pemetrexed versus placebo, where prespecified analysis for histology were performed, that patients with adenocarcinoma histology had better median PFS (4.5 versus 1.5 months, HR = 0.511; CI: 0.38–0.68; p < 0.0001) and median overall survival (16.8 versus 11.5 months; HR = 0.73; CI: 0.56–0.96; p < 0.026). The benefit was also significant for nonsquamous carcinomas classified as other, and for nonsquamous cell carcinoma overall, but not for large cell carcinomas or squamous cell carcinomas.14 Several phase II studies have also shown a benefit for pemetrexed in patients with advanced NSCLC with nonsquamous histologic subtypes.242,243 Nevertheless, a recent phase III trial, with primary end point as the assessment of quality of life, observed similar outcomes for patients treated with pemetrexed/carboplatin regardless of histology.244 Patients with adenocarcinoma or NSCLC-NOS (nonsquamous NSCLC histology) are the only patients who have been demonstrated to benefit from bevacizumab in combination with chemotherapy.245 Indeed, patients with squamous cell carcinoma are at greater risk of adverse events, and therefore, such patients have been excluded from receiving this drug by the Food and Drug Administration,17 but they are eligible for adjuvant therapy in ongoing trials.16

Very recently, a new predictive biomarker has been identified in patients with NSCLC, the EML4/ALK translocation. This translocation leads to an oncogenic constitutive activation of ALK.220,246,247 A recent study of 82 patients with NSCLC confirmed to have ALK fusion by FISH demonstrated a 57% overall response rate to crizotinib (PF-02341066), an inhibitor of MET and ALK, and the estimated 6-month PFS was 72%.248 De novo resistance mutations in the kinase domain of EML4-ALK have been reported to develop during ALK inhibitor therapy.249

Clinical Implications of Histology and Molecular Testing

Accurate histologic subtyping and EGFR mutation testing are important and should be included in the initial work-up of patients with advanced lung adenocarcinoma because it may guide treatment decisions. Whether other EGFR tests should be recommended (i.e., immunohistochemistry and FISH) and/or KRAS mutation as an indicator of TKI resistance is not yet clear.250,251 In addition to EGFR mutation analysis, additional molecular tests are in development and may be more useful when further clinical data support their use.

Surgically Resectable NSCLC

Twenty to 30% of patients with NSCLC are diagnosed with stage I to stage IIIA disease and, thus, may be amenable to surgical resection. Patients who undergo resection have differing prognosis based on pathologic stage. The recent IASLC staging project has demonstrated overall 5-year survival of 73% for stage IA, 58% for stage IB, 46% for stage IIA, 36% for stage IIB, 24% for stage IIIA, and 9% for stage IIIB.252,253 The introduction of adjuvant cisplatin-based chemotherapy represented a major step forward with a 5% increase in cure rate.254 Still, 27% of patients with stage IA
disease and 42% of patients with stage IB NSCLC eventually recur and die of their disease; there is no accurate way to predict which of these patients have poor-risk disease and are likely to recur. Similarly, 41% of patients with stage II NSCLC are cured by surgery alone and do not need any adjuvant therapy. Thus, an urgent need to identify factors which will select patients for adjuvant therapy, exists. Several predictive factors for better efficacy of adjuvant chemotherapy have been described in retrospective analyses of phase III randomized adjuvant studies. An example is low expression of the DNA repair genes excision repair cross-complementation group 1 for greater benefit from cisplatin-based chemotherapy, although this needs further validation.

Based on initial data showing striking differences in survival predicted by histologic subtyping according to this classification of lung adenocarcinomas in resected specimens, it is possible in the future that histology will play an important role in selecting patients for adjuvant therapy.

Clinical Recommendation

In patients with advanced lung adenocarcinoma, we recommend testing for EGFR mutation (strong recommendation, moderate quality evidence).

Remarks: This is a strong recommendation because potential benefits clearly outweigh harms. This recommendation assumes that correct classification by EGFR mutation status is associated with important benefit based on randomized phase 3 clinical trials of EGFR-TKI therapy, which demonstrate a predictive benefit for response rate and PFS, but not overall survival, and subset analyses of multiple additional studies.

Clinical Consideration for Good Practice

1. If molecular testing is planned, appropriate biopsy methods should be used to obtain sufficient tissue for both pathologic diagnosis and molecular analyses, and the specimens should be handled appropriately.

Clinical Research Recommendations

1. How can this histological and/or molecular classification improve our ability to estimate prognosis and optimize the selection of patients for a specific therapy?
2. What is the relative importance of histologic versus molecular data for identifying prognostic or predictive markers based on small biopsies and cytology versus resected specimens?
3. Is immunohistochemical testing using EGFR mutation-specific antibodies as predictive of response to EGFR-TKIs as EGFR mutations?
4. In advanced lung adenocarcinomas, are the prognostic and therapeutic implications of histology any different if the pathologic diagnosis is based on a combination of histology and immunohistochemistry (i.e., TTF-1 and/or p63) versus conventional light microscopy alone which is the basis for current data?
5. In metastatic lung adenocarcinomas, what are the clinical implications of any potential differences in molecular or histologic features compared with primary tumors?
6. What are the clinical, epidemiological, molecular, and histologic characteristics of never smokers with lung adenocarcinoma?

Molecular Features

There are several molecular observations that have important implications for lung adenocarcinoma patients: (1) EGFR mutation is a validated predictive marker for response and PFS with EGFR-TKIs in the first-line therapy in advanced lung adenocarcinoma. (2) Tumors with an EGFR mutation have been associated with a more indolent course. (3) EGFR and KRAS mutations are virtually mutually exclusive. (4) EGFR/KRAS mutation-negative cases may have detectable fusion of EML4-ALK.

Histogenetic Origins of Lung Adenocarcinoma Subtypes

Normal lung tissues, from which lung cancers arise, can be anatomically divided into two major components, the air-conducting system and the peripheral lung parenchyma where gases are exchanged. After generation of the two embryologic lung buds, repeated branching morphogenesis results in conducting airways and the subsequent development of the terminal sac and alveoli. During the later stages, the regulatory TTF-1 is ubiquitously expressed in the peripheral lung epithelial cells such as small bronchioles and alveoli. TTF-1 is potentially a lineage-specific survival oncogene of some lung adenocarcinomas. The peripheral bronchioloalveolar compartment (terminal bronchioles, alveolar ducts, and alveoli) also contains two potential tumor cells of origin, the Clara cells and type II pneumocytes, which together comprise the terminal respiratory unit (TRU) and give rise to tumors expressing TTF-1. These often manifest as a GGN on CT. The central conducting airways (bronchi) contain two potential candidate progenitor cells that give rise to tumors: the bronchial basal cells and the mucous cells.

These tumors are TTF-1 negative and demonstrate a solid appearance on CT. Hierarchical clustering analysis of lung adenocarcinoma based on the expression profile demonstrated two major clusters, which correspond to TRU and non-TRU-type adenocarcinomas and thus two major subsets of adenocarcinoma with distinct histogenetic origins.

It is hypothesized that a subset of lung adenocarcinomas undergoes progression from AAH to AIS to invasive carcinoma and that this may be a stepwise process triggered by multiple genetic changes that supplement those responsible for initiation of the malignant phenotype. Although EGFR and KRAS mutations are observed from the earliest stages including normal epithelium and AAH, to invasive adenocarcinoma, EGFR gene copy number changes become widespread later at the stage of invasion and metastases. EGFR, KRAS, and TTF-1 amplification are characteristic of this progression. p53 mutation is more often found in invasive compared with noninvasive adenocarcinomas. Nevertheless, p53 mutation has not been identified as a reliable prognostic marker or a therapeutic target.
Histologic Molecular Correlations

High-throughput analysis of DNA mutations has reshaped the molecular landscape of lung adenocarcinomas. DNA sequencing of 623 known cancer-related genes in 188 adenocarcinomas identified 1013 somatic mutations. In addition to confirmation of known tumor suppressor genes p53, P16INK4, and STK11/LKB1, newly described mutations in NF1 and RB1 were detected at a frequency of 10% each. There were two other important findings: (1) mutations were often detected in the tyrosine kinase gene family members EGFR, KRAS, ERBB4, EPHA4, EPH3, KDR, and FGFR4 that are potentially targetable by tyrosine-kinase inhibitors and (2) mutual exclusivity was demonstrated in several gene mutation pairs including EGFR/KRAS, EGFR/STK11, and NF1 and p53/ATM. Mutation frequency showed negative correlations between acinar, papillary, and BAC subtypes with mutations in LRP1B, p53, and INHBA. Nevertheless, these mutations showed significant positive correlations with the solid subtype (Table 5).

Many publications have studied the prevalence and specificity of KRAS and EGFR alterations in lung adenocarcinoma (Table 5). The frequency of KRAS and EGFR mutations is each 10 to 30% with higher EGFR mutation frequency in Asians, never smokers, and nonmucinous tumors, whereas KRAS mutations are most common in non-Asians, smokers, and in invasive mucinous adenocarcinoma.

AIS, adenocarcinoma in situ; MIA, minimally invasive adenocarcinoma; GGN, ground-glass nodule; EGFR, epidermal growth factor receptor; TTF, thyroid transcription factor.
tations in EGFR mainly affect the adenosinetriphosphate-binding pocket within the tyrosine kinase domain. The most common mutations result in an arginine for leucine substitution at amino acid 858 and in-frame deletions at exon 19. EGFR mutation status has been reported to be significantly associated with AIS, LPA, papillary, and micropapillary adenocarcinoma subtypes, although EGFR mutations can be seen in tumors with other histologic subtypes (Table 5). A large cohort of 806 NSCLC specimens showed a correlation between the presence of EGFR mutation and adenocarcinomas formerly classified as BAC or with BAC features (probably including AIS, MIA, and LPA),

Table 5 summarizes our present knowledge on the molecular features associated with predominant patterns of adenocarcinoma. The only example of a strong correlation between a histologic subtype and a set of molecular and biologic features is that of invasive mucinous adenocarcinoma (former mucinous BAC), which typically have KRAS mutations and lack of EGFR mutation.55,140,141–144 Most of these tumors are negative for TTF-1, and they may express MUC 2-5-6 because of their derivation from bronchiolar mucinous goblet cells.146,289

EGFR mutation is a specific target for therapy by EGFR-TKIs and is a validated biomarker of treatment response based on three recent phase 3 trials (see detailed explanation in Clinical Recommendation section)8–11 and multiple phase 2 trials.228–233 Recently described mutation-specific antibodies for the EGFR exon 19 deletion and L858R mutation seem to be much more reliable in predicting EGFR mutation status than previous antibodies, but they require further testing and validation in clinical trials.238–240 Specific acquired EGFR mutations such as T790M as well as, other genetic alterations in MET (amplification), ERBB3 (overexpression), and epiregulin (autocrine loop activation), account for approximately 50% of cases of TKI resistance.236,250,294–299

**Lung Cancers with ALK Translocations**

A minority of lung tumors harbor a small inversion within chromosome 2p giving rise to the transforming fusion gene EML4-ALK. No activating mutations in the kinase domain are observed; the dimerization of the fusion protein causes its activation.246 Epidemiological characteristics include prevalence in 5% of lung adenocarcinomas. Younger age, male gender, and never or light smokers may identify a population of patients with greater chance of harboring this aberration.153,220,248,300 A variety of histologic features are reported including acinar, papillary, cribriform, mucin production (intra- and extracytoplasmic), and signet-ring patterns.153,220,300–304

It is still at issue whether other histological types such as squamous cell carcinoma and mucoepidermoid carcinoma also contain EML4-ALK translocations. Detection of the EML4-ALK translocations can be difficult and can be approached with several methods including immunohistochemistry, FISH, and reverse transcription-polymerase chain reaction.153,248,249,300–303,305 Immunohistochemistry requires use of antibodies and methods that are validated to correspond well to EML4-ALK translocations, and it may serve as a useful screening method.153,302,306–308 Most tumors with EML4-ALK translocations are positive for TTF-1 and may be p63 positive.301,303 Tumors with EML4-ALK translocations seem to be mutually exclusive with EGFR and KRAS mutations and have a lower frequency of p53 mutations.153,247,300,301,303 Another ALK translocation involving KIF5B-ALK fusion has been recently identified in lung adenocarcinomas; however, at present, insufficient data exist to define its specific histological nature.302 De novo resistance mutations in the kinase domain of EML4-ALK have been reported to develop during ALK inhibitor therapy.249

**Lung Adenocarcinoma Gene Expression Analyses**

The messenger RNA genomic profiling of tumors can provide important information about pathogenesis, patient prognosis, and prediction of response to therapy in a fashion that complements histological evaluation. Unsupervised clustering analysis consistently shows three distinct groups of adenocarcinomas associated with tumor morphology69,261,309,310 and with lung developmental pathways. Beer et al.309 showed that tumors within the three clusters were significantly correlated with differentiation, stage, and morphology as classified by bronchial-derived or lepidic morphology. Borczuk et al.310 showed that invasive features were associated with the cluster containing more aggressive tumors. The three groups consisted of noninvasive and minimally invasive tumors (<5 mm); mixed-invasive and lepidic pattern tumors; and solid-invasive cancers. Motoi et al.69 demonstrated that the three clusters correlated strongly with former BAC, solid, and papillary subtypes, respectively. Takeuchi et al.261 showed that expression profile-defined adenocarcinoma subtypes were correlated with morphology and with normal lung developmental pathways. Morphologic analysis revealed two branches consisted of TRU-type adenocarcinomas, which are based on lepidic pattern and expression of TTF-1 and surfactant proteins, and non-TRU adenocarcinomas that lack these characteristics. TRU tumors were further divided into TRU-a and TRU-b classes. Functional annotation showed retention of normal peripheral differentiated lung features in the TRU types, which contrasted with the cell cycling and proliferation enriched annotation of genes associated with the non-TRU tumors.

Although EGFR mutations are found in association with papillary predominant adenocarcinomas (Table 5)69,98 and TRU-a tumors, whereas KRAS mutations are more frequent in the solid and TRU-b tumors, it is clear that oncogene mutation status is not a primary determinant of the molecular
subtypes as defined by gene expression profiling.\textsuperscript{311} Taken together, unsupervised clustering defines three morphologically distinct groups of lung adenocarcinomas. These include (1) AIS and MIA; (2) invasive nonsolid adenocarcinoma; and (3) invasive adenocarcinoma, predominantly solid.\textsuperscript{69,261,309,310} Thus, these molecular profiles provide biological plausibility for the proposed classification scheme that creates separate categories based on evaluation of lepidic pattern and other components, including solid pattern.

Recently Bryant et al.\textsuperscript{278} used the lung adenocarcinoma gene expression data from Shedden et al.\textsuperscript{99} together with complete pathological review to examine associations between 27 known cancer-related pathways and the adenocarcinoma subtype, clinical characteristics, and patient survival. Unsupervised clustering of adenocarcinoma and gene expression enrichment analysis reveals three main clusters and that cell proliferation is the most important pathway separating tumors into subgroups.\textsuperscript{278} Further, adenocarcinomas with increased cell proliferation demonstrate significantly poorer outcome and an increased solid subtype component. Interestingly, tumors with any solid component have decreased survival, when compared with tumors without a solid component. Significant associations between specific histologic subtypes, gene expression pathways, and clusters were also reported, some of these are included in Table 5. The consistency of these findings was demonstrated using two independent lung adenocarcinoma cohorts from Japan (\(N = 87\)) and France (\(N = 89\)) using the identical analytic procedures.\textsuperscript{278}

Tumor messenger RNA profiling is emerging as a source of clinically significant information regarding patient outcome after resection. Several predictors have been developed based on methodologically sound approaches that include independent validation.\textsuperscript{312–324} The results of these studies are heterogeneous in terms of the number of genes both in the predictors and in the specific genes included in each signature. This heterogeneity is expected given differences in study design, assay platform, tumor histology, and patient selection. A large, multicenter, blinded evaluation of eight independently derived genomic signatures of prognosis in 442 adenocarcinomas demonstrated that the addition of clinical covariates enhanced the performance of the signatures, relative to using gene expression alone.\textsuperscript{99} A method that relied on the correlated expression of 100 gene clusters to predict subject outcome produced relatively good performance with several other methods showing similar performance.\textsuperscript{99} Relatively higher expression of a cluster of 545 genes enriched for cell proliferation was associated with poor outcome. This study is a model for the careful handling of challenges inherent in translational cancer genomic studies and for its vast repository of clinical and pathologically annotated data. Independent prospective evaluation of the predictive accuracy of these signatures, prospective clinical trials, and application to small biopsy specimens\textsuperscript{200–203} will be required to extend this area of research.

### Copy Number Analyses of Lung Adenocarcinoma Subtypes

Multiple studies have defined lung adenocarcinoma subtypes by using techniques to assess DNA copy number changes.\textsuperscript{41,69,257,280,284,325–327} Adenocarcinoma subtype was examined in a comprehensive analysis using CGH by Aviel-Ronen et al.\textsuperscript{326} who contrasted former BAC and invasive mixed-type adenocarcinoma with former BAC features, most of which would probably be classified as invasive adenocarcinoma with predominant lepidic growth in the new classification. A large number of specific chromosomal alterations were detected such as gain at 1p, 2q, 5p, 7p, 11p, 11q, 12q, 16p, 16q, 17q, 20q, and 21q in both former BAC and the adenocarcinomas with lepidic growth. Although both types had similar chromosomal changes, the invasive adenocarcinomas with lepidic growth showed greater variability and frequency of chromosomal changes and with longer segmental alterations and deletions. Deletions were also more common in adenocarcinomas with lepidic growth and were observed mainly on 3p and 5q to a lesser extent on 4q and 6q. The genomic profile of former BAC seems to be distinguishable from that of invasive adenocarcinoma with lepidic growth, with the latter displaying greater genomic aberrations. This demonstrates a progression at the genomic level from former BAC to the invasive areas of adenocarcinoma with lepidic growth.

Weir et al.\textsuperscript{257} found the most common focal amplification event in lung adenocarcinoma involved chromosome 14q13.3 in 12% of cases and TTF-1, also known as NKX2-1 was identified in this region. Barletta et al.\textsuperscript{41} examined histologic correlations with amplification of the TTF-1 gene, and six cases demonstrated TTF-1 amplification among the 49 acinar, papillary, and solid subtypes but not in tumors classified formerly as BAC.

EGFR gene amplification was examined using FISH by Hirsch et al.\textsuperscript{284} who demonstrated that EGFR gene copy number detected by FISH is associated with improved response to gefitinib therapy in patients with advanced-stage former BAC and in adenocarcinomas with lepidic growth. A strong relationship between mutation and EGFR amplification was also reported by Cappuzzo et al.\textsuperscript{328} Conde et al.\textsuperscript{280} reported similar results with a higher percentage of mutations among adenocarcinomas with former BAC and papillary morphologies relative to adenocarcinomas without these features. Chang et al.\textsuperscript{327} used CISH and found that TKI responsiveness was significantly associated with EGFR mutation and adenocarcinoma morphology but only marginally with increased EGFR gene copy number. Other studies report similar findings, but the relationship between adenocarcinoma subtype and EGFR copy number changes is often not indicated.\textsuperscript{195,198,287} Motoi et al.\textsuperscript{49} was one of the first studies to examine this and found no strong correlations between adenocarcinoma subtype and EGFR amplification using CISH.

EGFR copy number analysis during the progression of adenocarcinomas has been examined.\textsuperscript{264,267} EGFR mutations precede copy number abnormalities. EGFR copy number heterogeneity was greater in the primary tumor than in corresponding metastases.\textsuperscript{264} EGFR amplification correlated with high histologic grade and/or invasive growth and was rare in the precursor lesions AAH and former BAC.\textsuperscript{267} Thus, tumors with these changes appear more aggressive. Zhu et
showed that using a multivariate Cox model, high EGFR copy number was both a significant prognostic factor for poor survival (HR: 1.93, CI: 1.09–3.44, p < 0.025) and a significant predictive factor of an erlotinib effect on survival (HR: 0.33, CI: 0.15–0.71, p < 0.005). The amplification of MET may be one possible mechanism associated with tumor resistance to erlotinib. Finally, the application of these types of FISH analyses to small diagnostic samples was examined by Zudaire et al. They found that more than 90% of cases of paraffin-embedded transthoracic FNA samples were suitable for FISH for both EGFR and c-MYC analyses. These studies suggest that even when limited tumor material is available, copy number analyses may provide prognostic information for EGFR amplification and an explanation for resistance to EGFR-TKIs for MET amplification. Nevertheless, EGFR mutation is more predictive of response to EGFR-TKIs than amplification.

**Multiple Pulmonary Nodules**

Several techniques have been tested to distinguish metastases from synchronous primary tumors including DNA microsatellite analysis, CGH, DNA mutation sequencing, immunohistochemistry, and gene expression analysis. The utility of these assays is enhanced by their potential application to small biopsy specimens. These approaches have not been prospectively validated; thus, their performance and efficacy in routine clinical practice remain to be established. Nevertheless, these molecular techniques offer promising new ways to help in the distinction of synchronous primary tumors from metastases in patients with multiple adenocarcinoma nodules, which is critical for accurate tumor staging, determination of prognosis, and for planning treatment.

**Molecular Differences in Metastases versus Primary Tumors**

There may be important differences between the primary tumor and metastases of lung adenocarcinoma both with respect to morphology and biomarker expression; however, more study of this problem is needed. The mutation status of metastases can be the same or different from that of the primary tumor and also among metastases, so a multidisciplinary approach is needed. The available data regarding EGFR mutations is mainly from tumor material collected at the time of diagnosis (either from the primary tumor or from metastases) and not from the point in time at which treatment with EGFR inhibitors is given.

**Molecular Prognostic Factors**

Biomarkers that can predict patient prognosis have been extensively sought during the past 20 years. Immunohistochemical markers for which meta-analyses have been done include EGFR, TTF-1, p21ras, HER2, p53, Ki67, BcIII, and cycloxygenase 2. All but EGFR, p21 ras, and cycloxygenase 2 were statistically significant by meta-analysis. Nevertheless, the magnitude of the association is generally weak with HRs that range from 1.13 to 1.57.

Meta-analyses showed that although prognostic impact of mutations of p53 or KRAS gene might be statistically significant, their impact was not strong enough to be recommended for routine clinical use. In contrast, there is a suggestion that patients who underwent surgical resection for lung adenocarcinomas that have EGFR mutations seem to have better prognosis in the absence of EGFR-TKI therapy than those without, based on two retrospective observational studies.

**Molecular Research Recommendations**

1. More investigation is needed of copy number variation, genomic, and proteomic markers for their relationship to clinical and pathologic variables.
2. EML4-ALK fusion gene needs further study, particularly in EGFR/KRAS-negative cases.
3. We recommend that research studies of molecular markers be based on well-annotated clinical and pathologic datasets, with adenocarcinomas diagnosed according to this classification.
4. MicroRNAs need further evaluation to determine whether they can be helpful in lung adenocarcinoma risk stratification and outcome prediction.
5. Investigations combining both genomic and proteomic studies are needed to determine whether they can provide more accurate subclassification of NSCLC and adenocarcinoma, and more precise information regarding the risk stratification, outcome prediction, and treatment selection for different subtypes of adenocarcinoma.

**RADILOGIC FEATURES**

A number of terms have been used to describe lung adenocarcinomas by CT imaging. In particular, for tumors that present as small nodules, the terms used have reflected the various ground glass (nonsolid), solid, or part-solid appearances that can occur. Largely based on the Fleischner Society glossary of terms and the recently suggested guidelines by Godoy and Naidich for subsolid nodules, we propose the following definitions: (1) a pure GGN (synonym: nonsolid nodule) as a focal area of increased lung attenuation within which the margins of any normal structures, e.g., vessels, remain outlined, (2) a solid nodule as a focal area of increased attenuation of such density that any normal structures, e.g., vessels, are completely obscured, and (3) part-solid nodule (synonym: semisolid nodule) as a focal nodular opacity containing both solid and ground-glass components. The Fleischner Society glossary of terms for thoracic imaging defines a nodule on a CT scan as “a rounded or irregular opacity, well or poorly defined, measuring up to 3 cm in greatest diameter” in any plane. If the opacity is greater than 3 cm, it is referred to as a mass. The ≤ 3 cm cutoff is in keeping with our concept of the maximum accepted size for the pathologic diagnosis of AIS and MIA. The term subsolid nodule has also entered common radiologic usage, referring to both part-solid nodules and pure...
GGN. Optimal evaluation of subsolid nodules requires thin-section CT scans (≤3 mm thickness) to assess the solid versus ground-glass components.

Radiologic Spectrum According to Histologic Subtype

AAH is the earliest preinvasive lesion for lung adenocarcinoma detectable by thin-section CT. It appears as a small (usually ≤5 mm), GGN (Figure 11). AAH characteristically appears as a very faint pure GGN usually measuring ≤5 mm. The pure GGN of AAH can be single or multiple.

AIS is best demonstrated at CT (preferably thin section) and sometimes can be seen on chest radiography. It is a noninvasive lesion and nonmucinous AIS presents typically as a pure GGN (Figure 12) but sometimes as a part solid or occasionally a solid nodule. AIS can be bubble like. Mucinous AIS can appear as a solid nodule or consolidation (Figure 13). The pure GGN of AIS usually appears at thin-section CT as slightly higher attenuation than the very faint GGN of AAH. AIS also can be single or multiple.

MIA is variable in its imaging presentation and is, as yet, not fully described, but a provisional description of the nonmucinous type at thin-section CT is a part-solid nodule consisting of a predominant ground-glass component and a small central solid component measuring 5 mm or less (Figure 14). Mucinous MIA (Figure 14) is less common than nonmucinous MIA and appears as a solid or part-solid nodule. There is an overlap among imaging features of AAH, AIS, and MIA.

Radiology Recommendation 1

When an opacity in the lung adenocarcinoma spectrum is either a pure GGN or part-solid nodule with a predominant ground-glass component, we recommend that the term BAC no longer be used. These tumors should be classified by the new terms: AIS, MIA, and LPA (strong recommendation, low-quality evidence).

Invasive adenocarcinoma is usually a solid nodule (Figure 15) but may also be part solid (Figure 16) and occasionally a GGN. A lobular pattern of ground-glass opacity (GGO) may occur (Figure 17). Bubble-like or cystic luencies in stage IA adenocarcinoma have been described as correlating with well-differentiated tumors and slow growth. Thick (≥2 mm) coarse spiculation has been associated with lymph node metastasis, vascular invasion, and decreased survival post resection. For stage IA adenocarcinoma presenting as a part-solid nodule, an extensive ground-glass component suggests a favorable prognosis. Histologically, the ground-glass component typically corresponds to a lepidic pattern and the solid component to invasive patterns. An intratumoral air bronchogram usually indicates a well-differentiated tumor. Absence of pleural retraction for stage IA adenocarcinoma is also a favorable prognostic sign. In solid adenocarcinomas, the presence of notches, or concave cuts on thin section CT, has been associated with poor differentiation on histology and adverse outcome.
Invasive mucinous adenocarcinoma, formerly called mucinous BAC, characteristically presents in imaging studies as a range of nodules to lobar replacement by a spectrum of patterns including GGO, mixed GGO/solid foci, or consolidation, but intraalveolar mucus may make the CT appearance solid or nearly solid (Figs. 18 and 19). The mucoid component may appear as homogeneous consolidation with soft-tissue attenuation that is lower than that of muscle. After administration of an intravenous iodinated contrast agent, vessels are well shown traversing these regions (CT angiogram sign). Overlap does occur between imaging features of mucinous and nonmucinous invasive adenocarcinomas.

Radiology Recommendation 2

For overtly invasive adenocarcinomas previously classified as mucinous BAC, we recommend they be separated from nonmucinous adenocarcinomas and be classified as invasive mucinous adenocarcinoma (strong recommendation, moderate quality evidence).

Remark: At CT, this entity is usually solid or mostly solid, has frequent air bronchograms, shows a lobar or multilobar distribution, and frequently consists of multiple nodular or consolidative opacities (former term multicentric BAC).

Size and Growth Rate of Lesions

AAH characteristically is  6 mm but in a minority of cases may be up to 12 mm. Growth is very slow. Although it has been suggested that a pure GGN less than 5 mm is so unlikely to become a cancer that it needs no follow-up, optimal frequency and duration of CT follow-up of a GGN of any size are as yet unclear.

AIS is variable in size, but most are 2 cm or less. Growth is very slow. Suspicious GGNs, i.e., 5 mm diameter, are usually followed by at least annual follow-up CT examination, and an increase in size or attenuation is regarded as a sign of probable progression to invasive disease. For sizes more than 10 mm, closer follow-up is indicated with CT every 6 months to 1 year. Nevertheless, all recommendations for following suspicious GGNs to date have been based on data from small observational studies and need further evaluation.

MIA has not yet been well defined in terms of imaging findings, in part, because the histopathologic definition is difficult, and little is known about size and growth rates, but most MIA are less than 2 cm. Invasive adenocarcinomas of the lung are variable in size and growth rates. For adenocarcinoma less than 2 cm, the smaller the tumor, the less likely there is to be vascular invasion. Size of an adenocarcinoma does predict metastatic disease to the central nervous system: for a node-negative adenocarcinoma of 2 to 6 cm, the probability of metastatic disease to the central nervous system has been reported as 0.14 for a 2 cm tumor, increasing linearly to 0.72 for a 6 cm tumor.

For small solid nodules suspicious for lung cancer at CT, the recommendations for follow-up per Fleischner Society guidelines are currently widely recognized. Nevertheless, these guidelines do not specifically address GGNs and part-solid nodules, as discussed by Godoy and Naidich.

Multiple Primary Lung Cancers

Multifocal lung adenocarcinomas are not uncommon, being found in up to 8 to 22% in surgically resected adenocarcinomas and 18% of adenocarcinomas detected in screening programs. Multiple lung adenocarcinomas can occur in the setting of multiple AAH, AIS, and invasive adenocarcinoma (Figure 20). Similarities or differences in attenuation may provide clues regarding the relative percentage of lepidic versus solid histologic components. Subsolid nodules are very rarely metastatic.

Positron Emission Tomography (Scanning)

Elevated standard uptake values (SUVs) on fluorodeoxyglucose positron emission tomography (PET) correlate with malignancy. PET is useful in staging, prediction of response to treatment, and surveillance after resection.
with cellular proliferation and aggressiveness of the primary cancer (Figures 15 and 19). Sensitivity of PET for AIS is usually very low. PET is commonly used for staging and follow-up of invasive adenocarcinoma, and for lesions of 7 mm or larger, SUV for adenocarcinoma of the lung tends to be lower than for other histologic types of lung cancer and correlate inversely with survival. PET may be more accurate than CT for assessing response to chemotherapy, although more studies are needed. For mucinous versus nonmucinous adenocarcinoma, after adjusting for size of the lesion, no significant difference in SUV has been found. For a small, well-differentiated adenocarcinoma of low fluorodeoxyglucose avidity (e.g., maximum SUV \(< 2.5\)), follow-up PET to assess change in SUV as a diagnostic tool unfortunately seems to be of only limited value.

**Magnetic Resonance**

Magnetic resonance has been investigated as a method for differentiating among small AIS, mixed invasive adenocarcinoma/AIS, and invasive adenocarcinoma. Magnetic resonance has been investigated as a method for differentiating among small AIS, mixed invasive adenocarcinoma/AIS, and invasive adenocarcinoma. In the studies by Ohno et al. and Tanaka et al., for the distinction of AIS/lepidic predominant (former BAC) from...
Radiology Considerations for Good Practice

1. Radiologists performing biopsies should obtain sufficient tissue not only for traditional microscopic analysis but also for immunohistochemical and molecular analysis.
2. Thin-section CT technique should be used for part-solid lesions, to record the size of (a) the solid component and (b) total tumor size, including both solid and ground-glass components (Figure 16).
3. Changes in shape, size, and attenuation help determine follow-up and when intervention is appropriate.

Radiology Research Recommendations

1. What is the natural history of single and multiple GGNs? The frequency of invasive transformation of these lesions is unknown.
2. How should tumor size be measured: single largest diameter, bidimensional, volume? For part-solid lesions, size of both the entire lesion and solid component should be mentioned, because prognosis as a function of size is not yet well established in terms of the dimensions of the solid component. Correlation of the measurement of the solid component of part-solid lesions and size of the invasive component at histopathologic assessment is also needed. Careful attention to thin-section CT technique to assess changes over time in sizes of small adenocarcinomas of the lung is warranted. Inter- and intraobserver differences among radiologists for measurements of the size of a nodule remain an important arena for inquiry. Volumetric measurements also offer promise for assessing changes in size of indeterminate nodules, but error—both human and computer—remains an issue for small GGN, including identifying a possible solid component (Figures 17B, C).
3. What is the CT attenuation according to the newly proposed lung adenocarcinoma histologic subtypes? CT histogram analysis suggests that attenuation characteristics may differ among AAH, AIS, and MIA. Further investigations of these lesions using quantitative analysis are in order.
4. In the setting of multiple adenocarcinomas, can careful description of the attenuation (e.g., relative extent of ground glass versus solid components) for each nodule assist in the determination whether the nodules are metastases versus synchronous or metachronous primary carcinomas, similar to the way comprehensive histologic subtyping is helpful pathologically?
5. How can this new classification impact CT screening? Screening may reveal small cancers early in their natural history, and cost/benefit issues, both medical and economic, remain an arena of active current research.
6. What molecular correlations can be made with the spectrum of radiologic patterns of lung adenocarcinoma? Not many studies have attempted correlation of imaging and molecular findings. EGFR mutations have been described as correlating with more than 50% GGO, with size less than 3.5 cm and with a high SUV level at PET of advanced-stage disease. Ki-67 has been described as associated with high SUV levels at PET and with dedifferentiation of the tumor.

Invasive adenocarcinoma, sensitivity was 86% and 97%, and specificity was 100% and 77%, respectively.

Imaging-Guided Percutaneous Needle Biopsy for Molecular and Immunohistochemical Correlations

Percutaneous imaging-guided needle biopsy, whether obtained by aspiration or as a core, allows molecular characterization from even minimal samples.

Radiology Recommendations

1. When an opacity in the lung adenocarcinoma spectrum is either a pure GGN or part-solid nodule with a predominate ground-glass component, we recommend that the term BAC no longer be used. These tumors should be classified by the new terms: AIS, MIA, and LPA (strong recommendation, low-quality evidence).
2. For overtly invasive adenocarcinomas previously classified as mucinous BAC, we recommend they be separated from nonmucinous adenocarcinomas and be classified as invasive mucinous adenocarcinoma (strong recommendation, moderate quality evidence).

Remark: At CT, this entity is usually solid or mostly solid, has frequent air bronchograms, shows a lobar or multilobar distribution, and frequently consists of multiple nodular or consolidative opacities (former term multicentric BAC).
SURGICAL FEATURES

The newly proposed adenocarcinoma classification, particularly introduction of the concepts of AIS and MIA, raises surgical issues to which no definite answer is available yet. This relates to sublobar resection for early-stage lung cancer, role of chest CT in selecting patients for sublobar resection, specific surgical approach for these lesions, extent of lymph node dissection, the role of frozen section analysis, and the treatment of multiple small lung cancers.

Is Sublobar (Limited) Resection Adequate Oncologic Treatment for Some Early Adenocarcinomas?

One of the main reasons for defining the concepts of AIS and MIA in this classification is to raise the question whether these diagnoses can be anticipated by a GGO appearance on CT when presenting as a small, solitary lesion and whether limited resection may be effective therapy for such lesions. Lobectomy is still considered standard surgical treatment for tumors 2 cm or less in size, which have a solid appearance on CT, because such tumors are invasive carcinomas. Whether there can be any change in this standard care for lesions that present with a GGO appearance on CT awaits the results of two randomized trials (Japan Clinical Oncology Group, JCOG 0802 in Japan and CALGB 140503 in North America) that randomize such patients to either lobectomy or sublobar resection. Recently, there have been numerous retrospective studies that have suggested that sublobar (limited) resection for early lung cancers may be adequate surgical treatment; however, these are not randomized trials. Most reports showed no difference in survival or in locoregional recurrence between lobectomy and sublobar resection for tumors 2 cm or less in size. Tumors with a GGN (GGO) appearance on CT are reported to have 100% disease-free survival at 5 years after complete resection.

Can CT be Used to Select Patients for Sublobar Resection?

In performing sublobar resections, several important factors affect the appropriateness of this intervention. These include the location (peripheral versus central), appearance (ground glass versus solid), and size (T1a versus T1b versus T2) of the tumor. CT images, especially obtained by high-resolution CT scan with thin slices, are indispensable to evaluate these factors, and recent studies show rather good image-pathological correlations. In recent studies correlating CT findings of GGOs with histopathology, many of these lesions, though not all, correspond to preinvasive, noninvasive component still needs to be defined. The predictive value of frozen section ranges from 93 to 100% but not all articles clearly report the accuracy of frozen section analysis. Evaluation of margins by frozen section may be problematic, especially when staple cartridge have been used on both sides. Scraping or washing of staple lines with subsequent cytological analysis has been attempted. When a sublobar resection is performed, frozen section analysis of an interlobar, hilar, or any suspicious lymph node is a useful staging evaluation, and when positive nodes are found, a lobectomy is indicated when there is no functional cardiopulmonary limitation.

Should a Systematic Lymph Node Dissection be Performed in Every Early-Stage Adenocarcinoma?

The necessity of systematic hilar and mediastinal lymph node dissection is based on the fact that approximately 20% of pulmonary adenocarcinomas ≤20 mm and 5% of cases ≤10 mm in size are reported to have nodal metastases. Lobe-specific nodal dissection, which limits dissection to the primary nodal regions draining the involved lobe, has been shown to be a potentially adequate alternative to complete systematic nodal dissection. A recently reported multicenter prospective clinical trial randomizing patients with intraoperatively staged T1–2N0 nonhilar N1 NSCLC to lymph node sampling versus systematic nodal dissection showed that systematic nodal dissection identified occult disease in 3.8% of patients but was not associated with a benefit in overall survival. These results should not be generalized to higher stage tumors. Recent studies also show that in some specific subsets of very early-stage adenocarcinoma, especially GGO lesions, systematic lymph node dissection is not always required.

Multiple Lesions

In the setting of multifocal lung adenocarcinomas, when there is no evidence of mediastinal lymph node invasion, multiple nodules are not a contraindication for surgical exploration. A standard treatment algorithm for multiple lesions has yet been established. Several factors have to be taken into consideration: number and size of the different nodules, synchronous versus metachronous lesions, ipsilateral versus contralateral, primary versus metastatic lesions, and specific nature (AAH, AIS, and MIA).
Surgery Research Recommendations

1. The precise role of limited resection has not been determined yet because of a lack of randomized prospective trials.
2. The extent of lymph node dissection remains controversial.
3. The accuracy of frozen section in assessing the presence of invasive adenocarcinoma and the accuracy of frozen section or cytology of resection margins in sublobar resections need to be investigated further, and specific guidelines for frozen section analysis should be developed to guide intraoperative decisions.
4. Treatment of multiple lesions has not been standardized.

CLASSIFICATION IN A LOW-RESOURCE SETTING

Although this lung adenocarcinoma classification is written to incorporate special stains and molecular techniques, it is understood that some patients will need to be managed without immunohistochemical or molecular data. This may occur in parts of the world where resources are limited, or it may happen in academic centers where the additional tissue required for special studies is not available. This section briefly outlines how this classification can be applied in such situations.

Pathologic Classification

In the absence of molecular, immunohistochemical, or histochemical testing, the diagnosis and subclassification of lung adenocarcinoma are based purely on light microscopic evaluation of pathologic material.

Resection Specimens

For resection specimens, the two situations where special stains may be useful include solid adenocarcinoma, for which mucin stains can help in the distinction from large cell carcinoma, and for which NE markers can help diagnose LCNEC. In the former situation, if an adenocarcinoma shows a pure solid pattern without acinar, papillary, or lepidic patterns, sometimes intracytoplasmic mucin can be seen on H&E stains. If this cannot be detected, the tumor should be classified as large cell carcinoma, mentioning that it was not possible to perform special stains. If a non-small cell carcinoma shows NE morphology and NE immunohistochemical markers cannot be performed, the tumor should be classified as large cell carcinoma with NE morphology and a specific comment should be made that the tumor could be LCNEC but that material was not available to confirm this immunohistochemically.

Small Biopsies and Cytology

For small biopsies, if clear glandular or squamous differentiation is seen morphologically, the tumor can be classified as adenocarcinoma or squamous cell carcinoma, respectively. If there is some level of uncertainty, this can be reflected by the phrase: poorly differentiated non-small cell carcinoma, favor adenocarcinoma (or squamous cell carcinoma), mentioning in a comment that special stains were not available, and this diagnosis is based purely on light microscopic morphology. If no morphologic features of glandular or squamous differentiation are seen, the tumor should be classified as poorly differentiated NSCLC-NOS.

Clinical, Radiologic, and Surgical Approach to Aid Management of Patients in the Absence of Molecular or Immunohistochemical Data

Evaluation of patients with lung adenocarcinoma should be no different if the diagnosis is established in the absence of special techniques.

Whenever possible, a chest CT extending to adrenals and liver should be used for radiologic evaluation of such patients. In a low resource setting, chest radiography may reveal the primary lung cancer, pleural effusions, and involvement of lymph nodes or bones; however, given the much lower resolution with radiographs compared with CT, an attempt to obtain a chest CT examination should be made for accurate diagnosis and staging of tumor when possible.

If patients diagnosed in low resource settings may subsequently have tissue tested with molecular or immunohistochemical studies, tissue should be managed appropriately to make this possible.

Clinical management of lung adenocarcinoma patients without information about molecular status such as EGFR or K Ras mutations consists of standard surgical and chemotherapeutic approaches based on tumor, node, and metastasis (TNM) staging.

IMPLICATIONS OF THIS CLASSIFICATION FOR TNM STAGING

There are several important implications of this new adenocarcinoma classification for staging that need to be considered for the next revision of the TNM classification. The changes relating to the concepts of AIS, MIA, and LPA currently used in breast cancer, but they would not be applicable to other histologic types of lung cancer. In addition, the comprehensive histologic subtyping approach to assessing invasive adenocarcinomas in this classification provides a useful approach to staging multiple adenocarcinomas.

1. AIS would be classified as Tis. Nevertheless, because carcinoma in situ (CIS) can occur with both lung squamous cell carcinoma and adenocarcinoma, these should be specified as Tis (squamous) or Tis (adenocarcinoma), similar to breast cancer where there is Tis for ductal CIS and Tis for lobular CIS.
2. MIA would be classified as T1mi, similar to microinvasive breast cancer, which defined as an invasive carcinoma with no focus measuring greater than 1 mm; however, the size for MIA is not greater than 5 mm.
3. Also, similar to breast cancer, the size T factor for adenocarcinomas with an in situ or lepidic component may best predict prognosis according only to the size of the invasive component rather than the way it is currently done including total tumor size including both the invasive and the lepidic or in situ components.
early-stage tumors, the tumor size T factor may need to be adjusted from total tumor size to only the size of the invasive component. This needs to be tested radiologically and pathologically by comparing survival according to total tumor size (GGG plus solid components by CT versus invasive versus in situ/lepidic components pathologically) compared with analysis only by the size of the solid or invasive component by CT and pathology examinations, respectively.

4. For multiple lung adenocarcinomas, comprehensive histologic subtyping can help in distinguishing intrapulmonary metastasis versus synchronous or metachronous primaries. The role of molecular testing in this setting is promising but needs further study.

Many of these concepts need to be tested vigorously in the next 5 years in both early- and advanced-stage lung adenocarcinoma to determine whether they are robust enough to warrant changes in the 8th Edition TNM classification.

ACKNOWLEDGMENTS

The authors thank Isabel Sulimanoff, MSKCC Senior Reference Librarian, for expert assistance with developing the search strategy and literature search and Drs. Holger Schumemann of the ATS Documents Development and Implementation Committee for advice about the systematic review and Thomas Barker, for administrative assistance.
